CONTENTS

VOLUME 1

Preface		xv
Chapter 1	Speciation in Diatoms: Patterns, Mechanisms, and Environmental Change <i>Joshua T. Cooper and John P. Masly</i>	1
Chapter 2	Sympatric Speciation of Island Plants: The Natural Laboratory of Lord Howe Island <i>Alexander S. T. Papadopoulos, William J. Baker and Vincent Savolainen</i>	37
Chapter 3	Speciation of Arabian Gazelles <i>Hannes Lerp, Torsten Wronski, Thomas M. Butynski and Martin Plath</i>	59
Chapter 4	Chromosome Plasticity, Adaptation and Speciation in Malaria Mosquitoes <i>Igor V. Sharakhov</i>	83
Chapter 5	Transcriptional Differentiation Across the Four Subspecies of <i>Drosophila mojavensis</i> <i>Luciano M. Matzkin and Therese A. Markow</i>	119
Chapter 6	Evolution of Male Courtship Songs in the <i>Drosophila buzzatii</i> Species Cluster <i>Cássia C. Oliveira, Maura H. Manfrin, Fábio de M. Sene and William J. Etges</i>	135
Chapter 7	Prezygotic Isolation in the Parasitoid Wasp Genus <i>Nasonia</i> <i>Maartje C. W. G. Giesbers, Sylvia Gerritsma, Jan Buellesbach, Wenwen Diao, Bart A. Pannebakker, Louis van de Zande, Thomas Schmitt and Leo W. Beukeboom</i>	161
Chapter 8	Where to Look for Speciation Genes When Divergence Is Driven by Postmating, Prezygotic Isolation <i>Jeremy L. Marshall</i>	189

Chapter 9	The Molecular and Evolutionary Basis of Hybrid Sterility: From <i>Odysseus</i> to <i>Overdrive</i> <i>Nitin Phadnis and Harmit S. Malik</i>	203
Chapter 10	The Role of Transposable Elements in Speciation <i>Eric T. Watson and Jeffery P. Demuth</i>	223
Chapter 11	Hybrid Incompatibility: Are Cellular Processes the Battlefields of Genomic Conflict? <i>Norman A. Johnson</i>	247
Chapter 12	Processes in Organic and Cultural Evolution <i>Börje Ekstig</i>	257
Chapter 13	Natural Selection and Diabetes Mellitus <i>Svetlana Shtandel</i>	301
Chapter 14	Genetic Drift among Native People from South American Gran Chaco Region Affects Interleukin 1 Receptor Antagonist Variation <i>Cecilia Inés Catanesi and Laura Angela Glesmann</i>	331

VOLUME 2

Chapter 15	Alternative Splicing and Neurological Disorders: Focus on Parkinson's Disease <i>Velia D'Agata, Valentina La Cognata and Sebastiano Cavallaro</i>	345
Chapter 16	Tau Alternative Splicing in Alzheimer's Disease <i>Gonzalo Emiliano Aranda-Abreu, María Elena Hernández Aguilar, Fausto Rojas Durán, Sonia Lilia Mestizo Gutiérrez and Jorge Manzo Denes</i>	373
Chapter 17	The Role of Splicing Factors in Cancer Prognosis and Treatment <i>Rebeca Martínez-Contreras and Nancy Martínez-Montiel</i>	383
Chapter 18	Nonsense-Mediated Decay and Human Disease <i>Nancy Martínez-Montiel and Rebeca Martinez-Contreras</i>	407
Chapter 19	Alternative Splicing Alterations in Alzheimer's Disease <i>T. A. Ishunina and D. F. Swaab</i>	427
Chapter 20	Plant RNA-Binding Proteins Implicate mRNA Processing in Absciscic Acid (ABA) Responses <i>Raquel F. Carvalho, Vera S. Nunes and Paula Duque</i>	453
Chapter 21	Comprehensive Analyses of Alternative Exons in Neuronally Differentiated P19 cells <i>Hitoshi Suzuki and Toshifumi Tsukahara</i>	475
Chapter 22	Identification of Genuine Alternative Splicing Variants for Rare or Long-Sized Transcripts <i>Seishi Kato</i>	495

Chapter 23	An Epigenetic View on Alternative Splicing <i>Gabriele A. Fontana, Aurora Rigamonti and Silvia M. L. Barabino</i>	515
Chapter 24	Alternative RNA Splicing and Regulation of Nitric Oxide Signaling <i>Iraida G. Sharina</i>	533
Chapter 25	Alternative Splicing by Analyzing a Human mRNA Diversity Using Data of FLJ Human cDNAs <i>Takao Isogai and Ai Wakamatsu</i>	551
Chapter 26	Alternative Splicing in Human Immune System and Autoimmune Diseases <i>Xiang Guo</i>	569
Chapter 27	Poly(ADP-Ribosyl)ation Regulates Alternative Splicing <i>Yingbiao Ji and Alexei V. Tulin</i>	583
Chapter 28	Patent Roadmap for the Biosensor Space <i>Mohamed C. Azeez, Unisha Patel and Dennis Fernandez</i>	595
Chapter 29	Avoidant/Restrictive Food Intake Disorder in a Female Patient Affected by Marfan Syndrome <i>A. P. Verri, A. Serio, M. Grasso, I. Brega and F. Clerici</i>	649
Chapter 30	Optimizing Oil Production in <i>B. napus</i> by Gene Stacking: Transgenic Co-Expression of <i>DGAT1</i> and Partially-Suppressed mtPDCK Cumulatively Enhance Seed Lipid Deposition <i>Elizabeth-France Marillia, Tammy Francis and David C. Taylor</i>	657
Chapter 31	Periodontitis: A Common Oral Disease the Genetic Susceptibility <i>Ying Zheng, You-Qiang Song and W. Keung Leung</i>	689
Chapter 32	Genomic Imprinting and the Brain: Neuron-Specific Switching of Gene Expression at Imprinting Regions <i>Masamitsu Eitoku and Hidenori Kiyosawa</i>	715
Chapter 33	Pharmacogenomics Focusing on Phase Two Metabolizing Enzymes <i>Kung-Hao Liang</i>	739

VOLUME 3

Chapter 34	Sexual Dimorphism in Insect Longevity: Insights from Experimental Evolution <i>Jelica Lazarević, Biljana Stojković and Nikola Tucić</i>	747
Chapter 35	Evidence of Natural and Sexual Selection Shaping the Size of Nuptial Gifts among a Single Bush-cricket Genus (<i>Poecilimon</i> ; Tettigoniidae): An Analysis of Sperm Transfer Patterns <i>J. McCartney, M. A. Potter, A. W. Robertson, K-G. Heller and D. T. Gwynne</i>	777

Chapter 36	Mate Choice Copying in Both Sexes of the Guppy: The Role of Sperm Competition Risk and Sexual Harassment <i>Claudia Zimmer, Alexandros S. Gavalas, Benjamin Kunkel, Janina Hanisch, Sara Martin, Svenja Bischoff, Martin Plath and David Bierbach</i>	795
Chapter 37	Sexual Selection under Parental Choice: Mating Strategies and Reproductive Success <i>Menelaos Apostolou and Marianna Zacharia</i>	813
Chapter 38	Melon Germplasm Characteristics, Diversity, Preservation and Uses <i>C. Mallor and A. Díaz</i>	825
Chapter 39	Preservation and Characterization of Woodland Grape (<i>Vitis vinifera</i> ssp. <i>sylvestris</i> GMEL.) Genotypes of the Szigetköz, Hungary <i>Gizella Jahnke, Zóra Annamária Nagy, Gábor Koltai, Edit Hajdu and János Májer</i>	845
Chapter 40	A Mini Review on Morphological and Genetic Diversity of Sweet (<i>Prunus Avium</i> L.) and Sour Cherry (<i>Prunus Cerasus</i> L.) Cultivars <i>Ioannis Ganopoulos, Panagiotis Madesis, Filippos A. Aravanopoulos, Athanasios Tsiftaris, Thomas Sotiropoulos and Konstantinos Kazantzis</i>	859
Chapter 41	Research on Purple Seed Stain of Soybean: Germplasm Screening and Genetic Resistance <i>Shuxian Li, Pengyin Chen, Bo Zhang and Grover Shannon</i>	871
Chapter 42	Somatic and Gonadal Tissue Cryopreservation: An Alternative Tool for the Germplasm Conservation in Wild Mammals <i>Alexsandra Fernandes Pereira, Alexandre Rodrigues Silva, Gabriela Liberalino Lima and Andréia Maria da Silva</i>	881
Chapter 43	Mitochondrial Gene Diversity of the Mega-Herbivorous Species of the Genus <i>Tapirus</i> (Tapiridae, Perissodactyla) in South America and Some Insights on Their Genetic Conservation, Systematics and the Pleistocene Influence on Their Genetic Characteristics <i>Manuel Ruiz-García, Armando Castellanos, Luz Agueda Bernal, Diego Navas, Myreya Pinedo-Castro and Joseph Mark Shostell</i>	909
Chapter 44	Strategies for Gene Prospecting of Plants in Response to Drought and Salinity <i>Deyvid Novaes Marques, Nicolle Louise Ferreira Barros, Diego Tuloza da Silva, Fabiano Melo de Brito and Claudia Regina Batista de Souza</i>	959

Chapter 45	Clinical Evidence and the Genetic Effects of Traditional Chinese Medicine for the Management of Proteinuria in Patients with Diabetic Nephropathy <i>Xiang Tu, XueFeng Ye, Quan Hu, ChunGuang Xie, ChengShi He, Ming Chen, James B. Jordan and Sen Zhong</i>	993
Chapter 46	Biochemistry and Genetics of Ansamycin Antibiotics <i>Amit Kumar Jha and Jae Kyung Sohng</i>	1017
Chapter 47	BRCA Gene Mutations Mediate Particularly High TNBC Risk by Defective Estrogen Signaling <i>Zsuzsanna Suba</i>	1045
Chapter 48	Genotype-Phenotype Relationships in Language Processes in Rett Syndrome <i>Alessandra Falzone, Antonio Gangemi and Rosa Angela Fabio</i>	1061
Chapter 49	Marfan Syndrome: A Rare and Sometime Very Disabling Genetic Disorder <i>Henry J. Mankin and Keith P. Mankin</i>	1079
Chapter 50	Marfan Syndrome and Periodontitis <i>Jun-ichi Suzuki and Yasunobu Hirata</i>	1093
Chapter 51	Combined Pectus Correction and Aortic Valve Sparing Root Replacement in Marfan Patients <i>Jean-Philippe Verhoye and Jacques Tomasi</i>	1099
Chapter 52	Severe Periodontitis in Marfan Syndrome <i>Naoto Suda</i>	1107
Chapter 53	Preimplantation Genetic Diagnosis for Marfan Syndrome <i>Anver Kuliev and Svetlana Rechitsky</i>	1113

VOLUME 4

Chapter 54	Anuran Cytogenetics: An Overview <i>Cíntia Pelegrineti Targueta, Stenio Eder Vittorazzi, Kaleb Pretto Gatto, Daniel Pacheco Bruschi, Ana Cristina P. Veiga-Menoncello, Shirlei M. Recco-Pimentel and Luciana Bolsoni Lourenço</i>	1117
Chapter 55	Human Cytogenetic Biomonitoring <i>Armanda Teixeira-Gomes, Solange Costa and João Paulo Teixeira</i>	1157
Chapter 56	Complex Karyotypes and Their Detection in Hematologic Malignancies: The Ongoing Role for Classical Cytogenetics <i>Helena Urbankova</i>	1177

Chapter 57	Natural Hybridization between Chromosomal Discrepant Species and the Role of Hybrid Speciation in the Genus <i>Astyanax</i> <i>Francisco de Menezes Cavalcante Sassi, Snaydia Viegas Resende, Rubens Pazza and Karine Frehner Kavalco</i>	1193
Chapter 58	Trichorhinophalangeal Syndrome (TRPS) Revisited <i>N. Selenti, M. Tzetis, E. Tsoutsou and H. Fryssira</i>	1203
Chapter 59	Epigenetic Modifications and Developmental Origin of Health and Diseases (DOHaD) <i>Jia Zheng and Xinhua Xiao</i>	1211
Chapter 60	Effects of Oxidative Stress on Epigenetic Mechanisms <i>Yildiz Dincer and Onur Baykara</i>	1225
Chapter 61	Epigenetic Modifications and Their Potential Role in Tumorigenesis <i>Muthu K. Shanmugam, Frank Arfuso and Gautam Sethi</i>	1241
Chapter 62	Alzheimer's Disease: An Insight from Epigenetic Perspective <i>Yildiz Dincer and Zeynep Sezgin</i>	1291
Chapter 63	Epigenetic Mechanisms in Cardiovascular Diseases <i>Mehmet Güven and Bahadır Batar</i>	1323
Chapter 64	Insights from Epigenomics Analysis of Sperm: Sperm Development and Male Infertility <i>Dheepa Balasubramanian, Eisa Tahmasbpour and Ashok Agarwal</i>	1361
Chapter 65	Epigenetics, Inflammation and Inflammatory Related-Diseases: A General Look <i>Müge Sayitoğlu and Yücel Erbilgin</i>	1383
Chapter 66	A New Molecular Approach to Obesity: Epigenetic Perspective <i>Burcu Bayoglu and Mujgan Cengiz</i>	1419

VOLUME 5

Chapter 67	Genetics and Evolution of Entomopathogenic Fungi <i>A. Garcia, M. Michel, S. Villarreal, F. Castillo, E. Osorio, M. T. García-Ruiz, F. Veana, A. C. Flores and R. Rodríguez</i>	1447
Chapter 68	Mitochondrial Population Genetics Inferences about the Phylogeography and Systematics of the Tayra (<i>Eira barbara</i> , Mustelidae, Carnivora) <i>Manuel Ruiz-García, Nicolás Lichilín-Ortíz, Yolanda Mejia, Juan Manuel Ortega and Joseph Mark Shostell</i>	1491
Chapter 69	The Precision Medicine and Precision Public Health Approaches to Cancer Treatment and Prevention: A Cross-Comparison <i>Stephen M. Modell, Sharon L. R. Kardia and Toby Citrin</i>	1525

Chapter 70	Neuropsychological Profile of People with Williams Syndrome (WS) <i>Anne-Sophie Pezzino, Nathalie Marec-Breton and Agnès Lacroix</i>	1547
Chapter 71	Preimplantation Genetic Diagnosis (PGD) for Chromosome Rearrangements <i>Chun Kyu Lim</i>	1569
Chapter 72	A Family-Based Association Study between the BDNF Gene and Attention Deficit Hyperactivity Disorder in Mexican Children and Adolescents <i>Alan López-López, Miriam Margot Rivera-Angles, Carlos Alfonso Tovilla-Zárate, Roberto Molina-Solís, Araceli Valencia-Hernández, Luis Gómez-Valencia, Thelma Beatriz González-Castro, Isela E Juárez-Rojop, María Lilia López-Narváez, Ana Fresan and Yazmin Hernández-Díaz</i>	1589
Chapter 73	Petroleum Microbiology and Genetics <i>Joana Montezano Marques, Carla Thais Moreira Paixão, Gabriel Villar Monte Palma Pantoja, Artur Luiz da Costa da Silva and Diego Assis das Graça</i>	1601
Chapter 74	Estrogen Activated ERs are the Chief Genetic Safeguards of Somatic and Reproductive Health in Mammals <i>Zsuzsanna Suba</i>	1633
Chapter 75	Motor Abilities are Related to Specific Genotypes in Rett Syndrome <i>R. A. Fabio, T. Caprì, M. Lotan, G. E. Towey and G. Martino</i>	1649
Chapter 76	A Longitudinal Study on the Development of a Boy with Fragile X Syndrome: Developmental Trends and Adaptive Changes in a Single Case Report <i>María Auxiliadora Robles-Bello, Nieves Valencia-Naranjo and David Sánchez-Teruel</i>	1669
Chapter 77	Cornelia De Lange Syndrome: A Review <i>Elizabeth A. M. Frost</i>	1683
Chapter 78	Cognitive-Behavioral Phenotype in Klinefelter Syndrome (KS) and Other Sex Chromosomal Aneuploidies (SCAs): Clinical Variability <i>A. P. Verri, C. D'Angelo, A. Cremante, F. Clerici, A. Mauri and C. Castelletti</i>	1697
Chapter 79	Transcranial Direct Current Stimulation (tDCS) and Cognitive Empowerment for the Functional Recovery of Diseases with Chronic Impairment and Genetic Etiopathogenesis <i>Antonio Gangemi, Tindara Caprì, Rosa Angela Fabio, Paola Puggioni, Alessandra Maria Falzone and Gabriella Martino</i>	1715

VOLUME 6

Chapter 80	Control of Force and Timing during Unimanual and Bimanual Tapping Movements of Adolescents with Down Syndrome <i>Nobuyuki Inui and Junya Masumoto</i>	1727

PREFACE

This 8 volume encyclopedia set presents important research on genetics. Some of the topics discussed herein include the speciation of Arabian gazelles, tau alternative splicing in Alzheimer's disease, Cornelia de Lange syndrome and autosomal dominant polycystic kidney disease.

Chapter 1 - Diatoms represent one of the most speciose groups of organisms within the microeukaryota— they occupy almost every aquatic niche worldwide, provide important functions within ecosystems as a major contributor of carbon dioxide fixation from the atmosphere, and also serve as a major contributor to the base of the aquatic food web. Despite this striking example of biodiversity and their ecological importance, the author know relatively little about the speciation processes at work in this group of organisms. In this chapter, the author review the patterns of speciation in marine and freshwater diatoms with respect to their paleontological, environmental, and genetic evolutionary histories. The author summarize the evidence for sex and hybridization among diatom species, and discuss recent work on understanding the mechanisms of reproductive isolation that limit gene flow in the microeukaryota. The author also discuss aspects of diatom genome evolution that provide clues to the genetic basis of speciation in this group. Finally, the author end with a discussion of a natural model system that presents a unique opportunity to address some of the outstanding questions in diatom speciation.

Chapter 2 - The evolution of new species without geographic isolation has received a great deal of attention over the past decade. The mechanisms that can lead to speciation of vascular plants in biogeographic sympatry fall broadly into three categories; speciation with ongoing gene flow (which is often, but not always, synonymous with ecological speciation), hybrid speciation and polyploid speciation. Here, with a particular focus on plant species, the author briefly review the concepts and research on sympatric speciation and its causes. Hybrid speciation and polyploid speciation have occasionally been dismissed as special (“simple”) cases of sympatric speciation and the author consider that, although they are distinctive, there are significant obstacles to overcome before new species can be generated by these mechanisms. As such they are deserving of as much research attention as is currently afforded to speciation with gene flow. The author argue that it remains important to continue identifying cases of speciation in sympatry, in order to gain a better understanding of how all of these mechanisms can drive speciation in restricted areas (rather than simply to quantify sympatric speciation per say) and the author elaborate on the usefulness of Lord Howe Island as a model system for speciation research with this in mind.

Chapter 3 - Gazelles are distributed across Africa and Asia and are adapted to arid and semi-arid environments. In this chapter, the author discusses potential factors promoting the divergence of lineages within this group (*i.e.*, speciation events). The most recent common ancestor of gazelles is thought to have emerged during the Miocene (12-14 Ma) and to have split into the extant genera *Nanger* and *Eudorcas* (both endemic to Africa), *Antilope* (endemic to Asia), and *Gazella* (present in Africa, the Middle East and Asia). Within *Gazella*, two major clades are thought to have evolved allopatrically: (1) a predominantly Asian Clade (*G. bennettii*, *G. subgutturosa*, *G. marica*, *G. leptoceros*, and *G. cuvieri*) and (2) a predominantly African Clade (*G. dorcas*/ *G. saudiya*, *G. spekei*, *G. gazella*, and *G. arabica*). At present, both clades meet in North Africa and, especially, in Arabia. Other splits in this group are better explained by adaptive speciation in response to divergent ecological selection. In both clades, parallel evolution of sister species pairs (a desert-adapted form and a humid mountain-adapted form) can be inferred; desert-dwelling *G. dorcas* in Africa and *G. saudiya* in Arabia have a sister group relationship with mountain-dwelling *G. gazella* in the Levant and *G. arabica* in Arabia. This relationship exists within Africa between the desert-dwelling slender-horned gazelle (*G. leptoceros*) and the mountain-dwelling Cuvier's gazelle (*G. cuvieri*) of the Atlas Mountains. A third species pair occurs in Asia; desert-dwelling goitred gazelle (*G. subgutturosa*) and mountain-dwelling chinkara (*G. bennettii*). These (ecological) speciation events correlate with ecology and behavior: the mountain forms being browsers, sedentary, territorial, and living in small groups, while the desert forms are grazers, migratory/ nomadic, non-territorial, and living in herds. Furthermore, cryptic sister species (*G. gazella*, *G. arabica*), with strikingly similar phenotypes, exist within presumed '*G. gazella*', alluding to a possible allopatric origin of this divergence following an isolation of humid mountain regions during hyper-arid phases. On the other hand, phenotypes within *G. arabica* tend to be variable, but are difficult or impossible to distinguish genetically.

Chapter 4 - Nonrandom distribution of rearrangements is a common feature of eukaryotic chromosomes that is not well understood in terms of genome organization and evolution. In malaria mosquitoes, chromosomal inversions—genome rearrangements that flip chromosomal segments by 180°—are often highly nonuniformly distributed among five chromosomal arms. These rearrangements are associated with epidemiologically important adaptations and, possibly, speciation in mosquitoes. A fundamental question is whether the genomic content of the chromosomal arms is associated with inversion polymorphism and fixation rates. This chapter highlights important differences in evolutionary dynamics of the sex chromosome and autosomes and reviews data about association between characteristics of the genome landscape and rates of chromosomal evolution. Recent studies suggest that a unique combination of various classes of genes and repetitive DNA in each arm, rather than a single type of repetitive element, is likely responsible for arm-specific rates of rearrangements. Additional factors, such as spatial constraints imposed by the nuclear architecture, may be responsible for the nonuniform distribution of rearrangements. Another important question is whether polymorphic inversions on homologous chromosomal arms of distantly related mosquito species nonrandomly share similar sets of genes. The available data indicate that natural selection favors specific gene combinations within polymorphic inversions when distant species are exposed to similar environmental pressures. This knowledge could be useful for the discovery of genes responsible for an association of inversion polymorphisms with phenotypic variations in multiple species. In this chapter, I also review the literature about a possible role of heterochromatin in speciation of malaria mosquitoes. The existing data demonstrate the

elevated evolutionary plasticity of the heterochromatic portion of the mosquito genome. Finally, I discuss the importance of high-quality genome assemblies for reconstructing a gene order-based phylogeny and studying mosquito evolution.

Chapter 5 - Local adaptation can play a fundamental role in the isolation of populations. While less well-studied than differentiation in sequence variation, changes in transcriptional variation during speciation also are fundamental to the evolutionary process. *Drosophila mojavensis* offers an unprecedented opportunity to examine the role of transcriptional differentiation in local adaptation. *Drosophila mojavensis* is a cactophilic fly composed of four ecologically distinct subspecies that inhabit the deserts of western North America. Each of the four subspecies utilizes necrotic tissue of different cactus host species characterized by distinct chemical profiles. The subspecies in Baja California, Mexico uses *Stenocereus gummosus* (Agria), in mainland Sonora it uses *S. thurberi* (Organ Pipe), in the Mojave Desert the host is *Ferocactus cylindraceus* (Red Barrel) and in Santa Catalina Island, USA, *Opuntia littoralis* (Prickly Pear) is the host. In this chapter the author examines how the adaptation to the different environmental conditions across the four subspecies have shaped their transcriptional profiles. Using complete *D. mojavensis* genome microarrays the author examined the transcriptome of third instar larvae from all four subspecies reared in standard laboratory media free of necrotic cactus-derived compounds. This experimental strategy focused on differences between constitutively expressed genes and not genes induced by necrotic cactus-derived compounds. The subspecies exhibited significant differential expression of genes that likely underlie the adaptation to different cactus hosts, such as detoxification genes (Glutathione S-transferases, Cytochrome P450s and UDP-Glycosyltransferases) and chemosensory genes (Odorant Receptors, Gustatory Receptors and Odorant Binding Proteins).

Chapter 6 - Acoustic signals produced to attract mates before, during, and after courtship are frequently involved with sexual selection, sexual isolation, and reproductive isolation in *Drosophila* spp. and other animals, yet few studies have revealed how courtship songs evolve in a larger phylogenetic context. Therefore, the author mapped different acoustic components of courtship songs in the monophyletic *Drosophila buzzatii* species cluster onto an independently derived *period* (*per*) gene + chromosome inversion phylogeny to assess the concordance of courtship song evolution with species divergence. These cactophilic flies are distributed throughout several biomes in southern South America and include the sibling species *D. buzzatii*, *D. koepferae*, *D. serido*, *D. borborema*, *D. seriema*, *D. antonietae*, and *D. gouveai*. All seven species produced two song types; primary and secondary pulse songs, except for *D. borborema* and *D. gouveai* that produced no secondary songs. Courtship songs were characterized by analyzing six commonly studied acoustic components including burst duration (BD), carrier frequency (CF), pulse length (PL), pulse number (PN), inter-burst interval (IBI), and inter-pulse interval (IPI). Significant intra- and inter-specific song variation was observed for BD, PN, and IBI, while CF, PL, and IPI varied in a more species-specific manner, albeit with some overlap. Thus, some song components may be better species recognition signals than others. Multivariate clustering analyses resolved all species into distinct, non-overlapping groups. Mapping individual song traits (BD, IBI, and IPI) as well as composites of these song variables onto our (*per*) gene + chromosome inversion phylogeny revealed no phylogenetic signal when different comparative mapping methods were used. Hence, the evolution of courtship songs in *D. buzzatii* cluster species was uncorrelated with the degree of species divergence. These findings reinforce previous observations that courtship songs evolve rapidly enough to erase any signature of evolutionary affinity between closely related animal species.

Chapter 7 - *Nasonia* (Hymenoptera: Pteromalidae) are small haplodiploid parasitoids of flesh- and blowfly pupae that have become model organisms for speciation research. The genus consists of four closely related species that harbor species-specific *Wolbachia* bacteria that cause postmating reproductive isolation. Antibiotic curing allows for interspecific crosses and genetic exchange between species which, together with haploidy of males, facilitates genetic analysis of fitness traits. In this chapter the author synthesizes the current knowledge on the different prezygotic isolation factors that act in the *Nasonia* genus, and on the genetic basis of these traits. A major prezygotic isolation factor is courtship behaviour. Species differ in male courtship behaviour, and there is large variation in interspecific mate discrimination depending on species pair. The author summarizes data on the strength of prezygotic isolation barriers between all possible species pairs and presents new data on mate discrimination in choice and no-choice experiments. In tests of reinforcement, the author found no stronger female mate discrimination of *N. vitripennis* strains occurring in microsympatry with *N. giraulti* compared to that of allopatric *N. vitripennis* strains. Additionally, the author presents data on the significance of cuticular hydrocarbon profiles for assortative mating in males and discusses other factors that may be involved in prezygotic isolation, including pheromone communication, within-host-mating and sneaking behaviour.

Chapter 8 - Not all genes are equally important during the process of speciation. This premise underlies a basic question in evolutionary biology – “Does divergence at any one gene, or set of genes, play a particularly important role in speciation?” The answer to this question may appear to be no for some forms of reproductive isolation, but there may indeed be ‘kinds of genes’ that routinely play a role in speciation when divergence is driven by postmating, prezygotic traits. Here, I outline the kinds of molecular pathways and interactions that underlie postmating, prezygotic phenotypes which ultimately points to the kinds of genes where the author should look for species-specificity. Interestingly, it is only when the author considers the entire system of interacting sex proteomes, cell structure, membrane dynamics, and physiological pathways that a picture of where species-specific interactions likely occur becomes clear. While this approach points to several kinds of pathways and gene types, a notable finding is that cell membrane receptors (like G-protein coupled receptors and receptor tyrosine kinases) that line the inside of the female reproductive tract and trigger post-copulation cell signaling should be considered the kinds of genes that routinely contribute to reproductive isolation and speciation when divergence is driven by postmating, prezygotic phenotypes.

Chapter 9 - Speciation, the process by which one species splits into two, involves the evolution of reproductive barriers such as the sterility or inviability of hybrids between previously interbreeding populations. One of the earliest intrinsic barriers to gene flow to evolve between geographically isolated populations is the sterility of hybrids of the heterogametic sex. The Dobzhansky-Muller model describes how hybrid incompatibilities that underlie intrinsic postzygotic reproductive barriers such as hybrid sterility may evolve. A major goal in speciation research is to identify the genes that underlie hybrid incompatibilities. The identification of such genes opens the door to understanding the molecular pathways which, when tinkered by evolution within species, lead to sterility in hybrids, and promises to reveal the biological forces that drive the evolution of hybrid sterility genes. While very few hybrid sterility genes have been identified so far, the idea that the evolution of DNA-protein interfaces driven by intragenomic conflict may cause hybrid sterility is gaining wider acceptance. Here the author describes how the molecular and evolutionary insights from two hybrid sterility genes

– *Odysseus* and *Overdrive* – have illuminated the role of heterochromatin in the molecular basis of hybrid sterility and the role of genetic conflict as a driving force in speciation.

Chapter 10 - With innovative DNA sequencing technologies has come a new appreciation for the content of animal and plant genomes. Overwhelmingly, a picture has been painted in which mobile and repetitive elements dominate the genomic landscape. Mobile genetic elements have recently been shown to contribute coding and regulatory sequences during their proliferation, leading to functional and regulatory novelty as well as element-mediated rearrangements coinciding with speciation events. Additionally, dormant elements occasionally erupt in bouts of excision and transposition in interspecific hybrids, resulting in a suite of maladaptive traits. The potential for mobile elements as key players in the evolution and diversification of genomes and species is immense yet in many respects transposable elements still remain the “dark matter” of the genome. This is particularly true of their role in speciation, and in order to fully appreciate their role, much work is still needed. In this chapter, the author investigate the evidence for transposable elements as drivers of diversification and speciation.

Chapter 11 - Recent studies suggest that much hybrid incompatibility results as a consequence of conflict between different components of the genome (genomic conflict). In this chapter, I argue that the battlegrounds for much of the conflict-driven hybrid incompatibility consist of various cellular structures and processes. These include the recombination machinery, centromeres and kinetochores, and heterochromatin and its associated proteins. I conclude with a call to integration between cell biology and evolutionary biology in the study of the evolutionary genetics of hybrid incompatibility.

Chapter 12 - In the present work, I give an all-embracing macroevolutionary perspective on processes of the evolution of life and culture on earth. First, I investigate a complementary form of natural selection that diverges from the traditional form in that it is acting independently of the external environment. This form of natural selection is found as a result of a mathematical analysis of the conditions for population growth. I extend my investigation as well to other evolutionary processes than the organic, such as the evolution of human language and the evolution of science, thereby suggesting other possible forms of underlying explanatory processes. I examine the concept of complexity and show that it implies new insights into the ways natural selection has been acting in forming the evolutionary and developmental processes. Especially, complexity is found to be growing in an accelerating mode, a process that is explained as the combined result of natural selection and a self-reinforcing feedback process. The use of the concept of complexity opens the possibility of construction of a new form of a Tree of Life, which, in contrast to traditional forms, combines complexity and time. Such an illustration of the evolutionary process explains the observation that most species live without great changes over vast periods of time. For species at the highest level of complexity there is no competition from species at still higher levels and these species can therefore, if conditions are beneficent, form new species at still higher levels. The process explains the emergence of new species and the general trend of evolution towards cumulatively higher complexity levels. The cumulative addition of species with successively higher complexity implies that the latest appearing species is the one of the highest level of complexity. At present, this species is the human species.

Chapter 13 - Advances in modern medicine enable a change in the tension of intragroup selection in human populations. Thus, implementation of insulin for type 1 diabetes mellitus (DM) treatment considerably lowered the selection tension for this symptom and converted it from the sub-lethal to the one with a lowered adaptability. Increasing variety of type 1 DM and

type 2 DM is being observed recently in different populations. Moreover, recently the heterogeneity of type 1 DM and type 2 DM has also been observed. The investigation was aimed to study the influence of the selection on the evolution of DM clinical forms. Global implementation of insulin therapy into type 1 DM treatment caused the prevalent increase of this disease. Currently, there is a positive selection trend for type 2 DM, which is the original cause for the prevalence increase within the population, and the negative one for type 1 DM determines its prevalence within the population approximately on the same level. Intra-population change of gene frequencies, susceptible for type 1 and 2 DM, predetermined the development of such DM clinical forms as LADA (latent autoimmune diabetes in adults). It also resulted in the increasing number of patients with an absolute insulin deficiency of type 2 DM, which is a more complicated form of this DM type. Polymorphisms association, changing the immune response and forming the susceptibility to type 1 (C1858T of the gene *PTPN22*, A49G of the gene *CTLA4*) and type 2 (E23K of the gene *KNJ11* participating in insulin insufficiency formation) with different DM forms illustrates the result of decreasing the selection tension against type 1 DM after insulin therapy implementation into the public health services practice.

Chapter 14 - Genetic variation is generally responsible for ethnic differences in certain diseases, including inflammatory processes. The antagonist of cytokine IL-1, IL-1Ra, has been widely studied among Caucasian and African populations for genetic polymorphisms, and interethnic differences have been documented. However, the variation and genotype distribution of polymorphisms from these genes among South American Amerindians are thus far unknown. The author present the results for a VNTR located in the IL-1Ra second intron, in a sample of 169 individuals belonging to 5 Native American populations from Argentina and Paraguay, identified as native according to their self designation, and their geographic location. The author also compare this data with the results obtained from a sample of non-native Argentinian people. Among the five known alleles of the VNTR, the author found only two (alleles 1 and 2) in the native populations from Gran Chaco, and heterozygosity was 19%. The allele 2 which is considered proinflammatory (IL-1Ra * 2) has been found in homozygosity at a considerable frequency among native individuals. However, the association of this allele with inflammatory disease previously demonstrated for other populations of the world, might not be acting in the same way for native people, probably due to local adaptation. This would indicate that the allele 2 will probably not have a negative influence on individuals of native origin who have homozygous genotype 2-2. On the contrary, few records on inflammatory disease are available for the native people. It seems that the increment on allele 2 is not related to any adaptive process but to genetic drift, that changes randomly the allele frequencies of different genetic regions along the genome. The effect of genetic drift has already been demonstrated with genetic markers located in autosomes, X and Y chromosomes. These results indicate that the author must be very cautious when studying populations that passed a process of genetic drift, which can become a confounding factor in epidemiological studies. This information will contribute to a future understanding of the association of this polymorphism with disease, and its incidence in different ethnic groups.

Chapter 15 - Alternative splicing (AS) is a fundamental mechanism of gene expression regulation that extremely expands the coding potential of genomes and the cellular transcriptomic and proteomic diversity. This dynamic and finely-tuned machinery is particularly widespread in the nervous system and is critical for both neuronal development and functions. Alternative splicing defects, therefore, frequently underlie neurological disorders. In

this chapter, the author will focus on Parkinson's disease (PD), the second most common neurodegenerative disorder worldwide. The author will provide a current overview on the impact of alternative splicing in PD by representing the multiple splicing transcripts produced from the major PD-linked genes and their regulation in PD states. Furthermore, the author will review the studies describing global splicing expression changes revealed by whole-genome transcriptomic approaches. The author will also summarize the current knowledge about the alternative splicing modulation in PD through non-coding RNAs (miRNA and lcnRNA) molecules. Assessing the role of alternative splicing on PD pathobiology may represent a central step toward an improved understanding of this complex disease.

Chapter 16 - The microtubule-associated protein (MAP) tau is essential for the development of neuronal cell polarity. Tau protein is preferentially localized in the axon, whereas MAP2, another neuron-specific microtubule-associated protein, is localized in the somatodendritic domain. Previous studies have demonstrated that the localization of these proteins depends, at least in part, on mRNA subcellular localization - of tau mRNA into the axon and MAP2 mRNA into the dendrite. Tau protein plays a pivotal role in the pathophysiology of Alzheimer's disease, in which its hyperphosphorylation promotes aggregation and microtubule destabilization. Tau undergoes alternative splicing, which generates six isoforms in the human brain, due to the inclusion/exclusion of exons 2, 3 and 10. Dysregulation of the splicing process of tau exon 10 is sufficient to cause tauopathy, and has been shown to be influenced by β -amyloid peptides, while there has been less research conducted on the splicing of other exons. This study found that the effects of β -amyloid (42) on the alternative splicing of tau exon 2/3 and 6 caused formed cell processes to retract in differentiated cells and altered the expression of exon 2/3 in cell culture. Expression of exon 6 was repressed under β -amyloid treatment. Although the molecular mechanism for this amyloid-tau interaction remains to be determined, it may have potential implications for the understanding of the underlying neuropathological processes in Alzheimer's disease.

Chapter 17 - Alternative splicing is a co-transcriptional mechanism that regulates eukaryotic gene expression that affects almost 90% of the human genes. In this mechanism, different combinations of exons and introns can be identified and removed from the pre-mRNA, allowing multiple mRNA configurations of joined sequences to arise from a single gene, increasing the coding potential of the genome. Alternative splicing events are catalyzed by a large complex known as the spliceosome, which is conformed by more than 300 proteins and ribonucleoproteins. At the catalytic core of the spliceosome, the small nuclear ribonucleoproteins (snRNPs) U1, U2, U4, U5 and U6 are found. The auxiliary factors responsible for the fine regulation of this mechanism include two major groups: the SR proteins and the hnRNP family. Malfunctions of alternative splicing events can affect the natural expression of a large number of transcripts, including several factors involved in apoptosis or cell survival, molecular processes intimately associated with cancer evolution. In many cases, specific splicing factors or mutated components of the splicing machinery are linked to an anomalous event. Moreover, a switch in specific splicing factors occurs in particular types of cancer where the concomitant outcome is the production of non-functional proteins with added, deleted, or altered domains affecting tumorigenesis. With all this evidence, several strategies have been developed to regulate alternative splicing in which central or auxiliary splicing factors are the target of modulatory molecules. Given the combination of elements needed to regulate alternative splicing, the mechanisms underlying the functional and physiological

implications of these tools are also diverse. Collectively, these strategies are intended to improve cancer prognosis, therapeutic and treatment.

Chapter 18 - The precise control of protein production is essential for the appropriate cell physiology and survival. However, single mutations or accidentally introduced errors can occur during the flow of genetic information. In eukaryotic cells, some messenger RNA (mRNA) molecules leave the nucleus after splicing but further mechanisms are involved in the ultimate outcome of the correspondent protein. One of such systems corresponds to the mRNA surveillance network that includes nonsense-mediated mRNA decay (NMD), an important quality control system that ensures the accuracy of transcripts, to maintain a healthy cellular homeostasis. NMD eliminates anomalous mRNAs harboring premature termination codons (PTCs) to prevent the production of potentially harmful truncated proteins, but it can also regulate the steady state of many physiological mRNAs. Targets for NMD are sometimes linked to mutations or introduced errors but the vast majority can be generated as a result of alternative splicing. The key components required for NMD include the UPF and SMG proteins. These factors interact with a set of proteins (the exon junction complex or EJC) that are deposited just upstream of exon-exon junctions after mRNA splicing and orchestrate a regulated mechanism in order to identify PTCs and either sequester these mRNAs or target them for degradation. Some of these factors are linked to particular disorders and could be modulated in order to correct the defect. The NMD pathway is physiologically and medically important, because an escape from NMD can result in severe clinical phenotypes. Consistent with this, it is estimated that more than 60% of human genes have alternatively spliced products that generate at least one PTC isoform and that approximately 30% of inherited genetic disorders are caused by nonsense mutations or by frameshifts that generate nonsense codons. Initially associated as a genetic cause for beta-thalassemia, the NMD process has expanded from the haematopoietic system and it has reached different kind of human disorders, including cystic fibrosis, Duchenne muscular dystrophy, Hurler syndrome, recessive spinal muscular atrophy and polycystic kidney disease. Finally, it is predicted that some cancers are aided by NMD and the repression of this mechanism may be a potential target for the treatment of certain cancers. In this regard, pharmacological agents have been developed for the treatment of diseases caused by premature stop mutations, including aminoglycosides, but the whole therapeutic potential of NMD targets to correct genetic disorders remains to be exploited.

Chapter 19 - Alzheimer's disease (AD) is the most common type of dementia in the elderly population with a higher prevalence in women. Memory impairment and cognitive decline in AD are primarily linked to its neuropathological hallmarks, i.e., cholinergic neuronal atrophy and death, presence of intraneuronal neurofibrillary tangles and accumulation of amyloid β ($A\beta$) deposits within the extracellular senile plaques. Consequently, genes encoding $A\beta$, tau and proteins involved in $A\beta$ processing received the most careful scientific attention. However, a growing body of evidence suggests that AD pathogenesis is not limited to the changes of AD genes' expression, but also depends on their alternative splicing. Therefore, the present review focuses on data concerning alternative splicing changes in AD. First of all, pivotal AD genes (APP (amyloid precursor protein), tau, presenilin 1 (PS-1) and 2 (PS-2) and apolipoprotein E (APOE)) have a number of splice variants with divergent functions that are differentially expressed in AD and normal brain tissues. Second, alternative splicing of genes involved in $A\beta$ processing and metabolism is also affected in AD. This group includes BACE-1 (β -site APP cleaving enzyme 1), nicastrin and APH-1 which are components of the γ -secretase complex, AIDA-1 (protein that binds to the intracellular domain of $A\beta$ PP following cleavage by γ -

secretase; FE65 (binds to the cytoplasmic tail of β PP). Finally, splice variants of such candidate AD genes as acetylcholinesterase (cholinergic deficit is one of the central mechanisms in AD development), estrogen receptor α (ER α) (estrogen deficiency is one of the predisposing to AD factors), BDNF (brain derived neurotrophic factor that is crucial for neuronal survival and synaptic transmission) and its receptor TrkB, excitatory aminoacid transporter 2 (EAAT2) (colocalized with tau in dystrophic neurons), genes of the ion channels and neurotransmitter receptors, synapsin, RCAN-1 (regulator of calcineurin), neuronal GFAP, ubiquilin-1 (related to the proteasomal degradation of proteins and interaction with PS-1 and PS-2) and genes involved in the regulation of the cell cycle and apoptosis (CIZ1, DENN/MADD) should be considered as important elements of the AD pathogenesis. Together, these data show that a lot of changes in alternative splicing are intimately linked to AD, which should be, thus, considered as a disorder with compromised and disregulated splicing events.

Chapter 20 - Posttranscriptional control of gene expression is crucial for biological processes. In particular, alternative splicing allows the same gene to produce multiple proteins and is thus a key generator of functional complexity. This posttranscriptional regulatory mechanism is a prevalent feature of eukaryotic genomes, being currently estimated to occur in over 50% of plant genes. RNA-binding proteins (RBPs) are known to control many aspects of RNA metabolism, from pre-mRNA splicing to the transport and stability of mRNA transcripts. The Arabidopsis and rice genomes contain about 200-250 genes predicted to encode RBPs, but few of these proteins have been characterized in plants. As sessile organisms, plants are continuously exposed to environmental challenges that affect their growth and development. The phytohormone abscisic acid (ABA) is crucial in the coordination of plant responses to various abiotic stress factors. Interestingly, several RNA-metabolism genes have recently been implicated in the ABA pathway, providing a link between mRNA processing and ABA-mediated plant stress responses. Indeed, the loss- or gain-of-function of genes encoding different classes of RBPs directly involved in constitutive and alternative pre-mRNA splicing, such as snRNP factors or SR and hnRNP proteins, has been shown to result in striking ABA-response plant phenotypes. Functional roles in ABA biosynthesis or signaling have also been reported for other RBPs, including cap-binding proteins, RNA helicases, pentatricopeptide repeat proteins or poly(A) processing enzymes. Taken together, these data support the notion that posttranscriptional networks act as central coordinators of plant stress responses, namely by targeting key components of ABA signal transduction machinery. Future identification of the direct targets of these RBPs should uncover the molecular mechanisms underlying the mode of action of these proteins in the regulation of the ABA pathway.

Chapter 21 - Alternative splicing occurs in most human genes and contributes to protein diversity by producing multiple mRNAs from each gene. Many of these alternative isoforms are expressed in a spatio-temporal manner and play important functional roles in many biological processes including neuronal events. Here, neuronal-specific splicing was comprehensively investigated by using P19 cells. GeneChip Exon Array analyses were performed of total RNA purified from cells during different stages of the differentiation process. Nine filtering conditions were used to efficiently and readily extract alternative exon candidates. A total of 262 candidate exons (236 genes) were obtained. Semi-quantitative RT-PCR results of 30 randomly selected candidates suggested that the expression levels of 87% of the candidates were at least 2-fold different between undifferentiated and differentiated cells. Gene ontology and pathway analyses also showed that many of these 236 candidate genes played important roles in neuronal events. These results suggested that this novel method to

determine alternative exons was successful and efficient. In addition to the known neuronal functions, informatics analyses demonstrated that alternative splicing events of 11 candidate genes played important cell cycle functions. These results suggest that this novel method also provides a way to determine the functional roles of previously unknown alternative splicing events.

Chapter 22 - Only sequence analysis of full-length transcripts can identify genuine alternative splicing variants. However, it was difficult to obtain full-length cDNAs for rare or long-sized transcripts. Recently, the author have developed a powerful method, named a vector-capping method, to construct a size-unbiased full-length cDNA library containing rare or very-long-sized cDNA clones with >10kbp inserts. The characteristic of the full-length cDNA contained in this library is that the intactness of the 5'-end capped site sequence of the cDNA can be assured by the presence of an additional dG at its 5' end. Since this full-length cDNA is derived from a single mRNA, this library enables us to perform in-depth analysis of genuine alternative splicing variants. Using the vector-capping method, the author prepared full-length cDNA libraries from human retina-derived cell lines and analyzed the full sequence of the clones. As a result, the author found many novel alternative-splicing variants for rare or long-sized transcripts. In this chapter, I show the examples of these variants including very-long-sized transcripts with >7kbp that were identified by us for the first time.

Chapter 23 - Genome-wide analysis indicate that alternative splicing of mRNA precursors (pre-mRNAs) affects the vast majority of human genes. Alternative splicing provides a fundamental mechanism to increase transcriptome complexity, allowing the production of two or more mRNA variants that often encode proteins with different, sometimes opposite functions. Its importance is underscored by the observation that misregulated alternative splicing can lead to human diseases. Pre-mRNA splicing has long been known to be regulated by *cis*-acting sequence elements and *trans*-acting protein factors. In higher eukaryotes, it mostly occurs co-transcriptionally so that it is not surprising that a role for chromatin and epigenetic factors in the regulation of exon inclusion is now emerging. In this review, the author will discuss the most recent findings on the roles played by chromatin structure on the modulation of the cotranscriptional splicing reactions. In particular, the author will focus our attention on how the modulation of the transcribing RNA polymerase II, the changes in nucleosome architecture and the presence of different histone modifications contribute to the regulation of the splicing process.

Chapter 24 - Alternative splicing expands transcriptome diversity and allows cells to meet the requirements of an ever-changing extracellular environment. It has been more than 30 years since nitric oxide (NO), a gaseous free radical, was recognized as a critical physiologic signaling molecule. Since then the list of known NO-directed functions has grown substantially to include regulation of smooth muscle function in vascular and gastrointestinal systems, inhibition of platelet aggregation and adhesion, neurotransmission and neuromodulation, regulation of cellular respiration and cytotoxicity, mitochondrial biogenesis and, immune defense. However, the importance of alternative splicing in regulation of enzymatic components of NO signaling pathway started to emerge only recently. Our understanding of the mechanisms governing this process remains very limited and awaits systematic investigation. In this chapter the author will attempt to summarize the available information on alternative splicing of major enzymes mediating canonical NO transduction through the secondary messenger cGMP. The author will highlight evidence accumulated from different laboratories that suggest splicing of enzymes in the NO/cGMP pathway, including nitric oxide

synthases, heterodimeric soluble guanylylcyclase and cGMP-dependent protein kinase, is very complex and strongly affects NO signaling in response to various environmental cues. Future studies will certainly bring new, exciting insights into the role that alternative splicing plays in NO/cGMP biology.

Chapter 25 - Genes could produce multiple protein-coding transcripts by alternative splicing (AS). It was known that AS is related to several diseases in generating biological and functional diversity. So, analysis of the mRNA diversity of genes would be important for understanding gene function. Previously, we obtained 1.46 million human full-length cDNAs (FLJ cDNA) and sequenced their 5'-ends. The author selected approximately 55 thousand cDNAs from FLJ cDNA and sequenced completely. Our FLJ cDNAs were constructed by an optimized oligo-capping method. Thus, by using 5'-EST data, a lot of valuable information was obtained regarding the diversity of the transcription start site (TSS) and amino acid sequences at the N-terminal ends of proteins. The author found that alternative TSSs were utilized for tissue-specific expression. Using this data, the author constructed FLJ Human cDNA Database ver. 3.2, <http://flj.lifesciencedb.jp>. But, a lot of AS-related information still remains to be extracted from our 1.4 million cDNA resources. From a huge number of human sequence information, the author selected only the reliable cDNAs for the analysis of the mRNA diversity. And, the author developed probes which can analyze the mRNA diversity. As a result, by comparing our constructed 5,784 pairs of independent probes, the author are able to detect the expression profiles of splicing patterns in 3,413 genes. Moreover, using these probes, the author analyzed the mRNA diversity of genes after inducing neuronal differentiation in human NT2 teratocarcinoma cells using all-trans retinoic acid (RA). Analyses of NT2 cells identified 452 RA-responsive genes. The mRNA diversity analysis revealed that the rate of genes that showed AS in their N-terminus, internal region, C-terminus, is almost the same, respectively.

Chapter 26 - Alternative splicing of pre-messenger RNA is nearly universal, involving more than 90% of human genes. It's an essential step in gene expression and responsible for much of the proteome diversity in mammalian genomes. The immune system requires a great diversity of functional proteins and immune cells need to respond to various foreign invasions rapidly. Alternative splicing provides one more layer of regulation that is essential for the function of human immune system. Many immune genes have been found to undergo alternative splicing, which plays an important role in the regulation of immune cell activation and function. Dysregulated splicing has been shown to be involved in various immune disorders, such as systemic lupus erythematosus (SLE) and rheumatic arthritis (RA). It may be a direct cause of the disease, or a modifier of disease susceptibility and severity. Further understanding of how alternative splicing may be used as a general mechanism in immune response is essential for our research in the pathophysiology of autoimmune diseases and development of new therapeutics for those diseases. This chapter provides an updated review about alternative splicing in human immune system as well as the relationship between dysregulated splicing and autoimmune diseases, particularly SLE and RA.

Chapter 27 - Poly(ADP-ribosyl)ation is a major post-translational modification performed by Poly(ADP-ribose) Polymerases (PARP1). PARP1 utilizes NAD as the substrate to synthesize a long linear and branching poly(ADP-ribose) (pADPr), ranging in length from 2 to 200 units of ADP-ribose. PARP1 can modify a variety of proteins by attaching pADPr to the target proteins in either a covalent or noncovalent manner. In this way, Poly(ADP-ribosyl)ation is involved in a number of biological processes, including transcription regulation, stress responses, and apoptosis. Recent studies have demonstrated that several splicing factors,

including hnRNPs and S/R proteins, are poly(ADP-ribosyl)ated via noncovalent binding by PARP1. Here, the author describe how poly(ADP-ribosyl)ation regulates alternative splicing by modulating the activities of these splicing factors. In addition, the author discuss a possible role of PARP1 in coupling transcription with splicing.

Chapter 28 - Genetic and behavioral data mining will revolutionize health/lifestyle delivery and outcomes, in much the same way the Internet delivered meaningful social outcomes by providing the infrastructure for information to be collected and connections to be made in ways that had not been possible hitherto. Genetic databases and lifestyle correlations via the cutting edge field of bioinformatics, wearable technology and personalized medicine will be the next echelon of information to be reconnoitered and used through the Internet to enrich our lives. Thanks to smart phones and wearable technology, it will all commence from the palm of our hands. In this review, the author will spotlight the emerging fields of bioinformatics, personalized medicine and biosensor technology: historical insights, current issues, and future trends. In particular, the author will embark on an in-depth look into the sub-fields of personalized medicine and wearable systems for health and lifestyle management. The health-sector, being information intensive, will exploit IT-led platforms that capture personalized health data in real-time and have connectivity with a cloud backbone to intelligently process the information to deliver real-time analytics and actions. Various roadmaps are presented offering aggressive offensive and defensive IP strategies and solutions to companies in the bioinformatics and biosensor space. How does current patent law and policy in the wake of the AIA reforms and Supreme Court decisions in *Alice* and *Mayo* impact on this field and on the strategic guidepost? What's more, the author will reopen the patent troll reform debate: will it create a sweeping sea change, or be just another talking point. How do the sweeping provisions of Obamacare touch upon the field of wearable health systems and bioinformatics? Moreover, how can the author reconcile proprietary value with the growing trends of the open-source movement and the big health data initiatives that lie at the intersection of private and non-profit sectors? Finally, all of this big health data begs an inquiry into issues of privacy and a host of other ethical concerns. With the right strategies in their IP toolkit, bioinformatics and wearable startup companies will not only bolster their current patent position, but also be able to leverage it into a significant competitive advantage. More importantly, the broader public will be able to avail themselves of the utility of these flash-bulb popping innovations that promise to capture personalized health data in real-time to deliver targeted and improved health outcomes.

Chapter 29 - Marfan syndrome is a heritable disorder of connective tissue that is transmitted as an autosomal dominant trait and is characterized by the mutation in the fibrillin 1 gene (FBN1). At present, the diagnosis of Marfan syndrome, based on Ghent criteria, considers both clinical evaluation (in which it is possible to observe alterations in eye, osteoarticular apparatus and cardiovascular system) and genetic evaluation (that reveals a FBN1 gene mutation). Moreover, the author take into account the presence of affected relatives suffering of the same syndrome. The diagnosis of Marfan syndrome is often complex because of the evolution of the phenotype with age and because of the inter-individual variation in the clinical presentation even among the affected family members. According to a recent review, Marfan syndrome is often associated with a range of psychiatric problems like anxiety disorders, depressive disorders, schizophrenia, neurodevelopmental disorders (autism spectrum disorder and attention deficit/hyperactivity disorder) and eating disorders. The author report a 16 years old female patient (MF) (kg 43, H 165 cm, BMI 16.9) who came to our outpatient service for a selective feeding successively diagnosed as Avoidant/Restrictive Food Intake

Disorder (ARFID; DSM 5). “Selective feeding” refers to children who restrict the ingestion of food to a limited number of “favourite” foods, typically five or six different foods. ML., indeed, eats only pasta, sweets and a few other foods. Beyond the altered feeding behaviour, she was diagnosed with a mild intellectual disability (IQ=57; VIQ=61; PIQ=62) and reduced adaptive levels in the socialization and communication domains of the Vineland Adaptive Behavior Scales (VABS). This patient presented ligamentous laxity, long-limbed body habitus suggestive for Marfan syndrome. Therefore, she was addressed to the cardiologist: the echocardiographic evaluation showed mild dilatation of aortic root, with rectilinear sinotubular junction and enlarged ascending aorta (z score=2). Z-scores of the aortic root at the level of the aortic annulus, sinuses of Valsalva, sinotubular junction, and ascending aorta measured from the parasternal long axis in diastole using leading-edge-to-leading-edge technique. The eye examination was normal. Sanger sequencing of the FBN1 gene identified the c.7501G>A (p.Val250Ile) variant/mutation. The missense mutation/variant is not reported in UMD, Ensemble, Exome variant server and dbSNP. The SIFT, PolyPhen2, Mutation Tester (software tool) for predicting damaging of missense mutations and variants gave the following results: PolyPhen2: benign; Mutation Tester: disease causing, SIFT: tolerant. Her mother carries the same mutation. ML. is affected by ARFID, (mild) intellectual disability and adaptive disorders often associated with Marfan syndrome, confirming and extending the results obtained in the review previously described. Moreover, the author underline the importance in multidisciplinary diagnosis and care (also) in these cases.

Chapter 30 - The author have previously shown that introduction of single genes encoding diacylglycerol acyltransferases (*DGAT1s*) or partially-silenced mitochondrial pyruvate dehydrogenase kinase (*mtPDCK*), each had the capacity to enhance seed oil content in *Arabidopsis*. In the current study, the author report the cumulative effects of expressing a two-gene stack: a site-directed mutagenized *DGAT1* from *Tropaeolum majus* (*TmDGAT1* Ser¹⁹⁷-to-Ala¹⁹⁷) and an anti-sense *mtPDCK* from *B. napus* (*A/S mtPDCK*) introduced into *B. napus* cultivar DH12075 to alter seed oil content. Compared to plasmid-only controls, the best lines of the two-gene construct showed, on average, a 23.6% proportional increase (11.6% net increase as % of DW) in oil content which is near-additive to the best results obtained in transgenic experiments with the single genes. These findings demonstrate the utility of stacking two specific transgenes controlling the key steps in two very different metabolic streams-mitochondrial carbon flux (*mtPDCK*; “push”) and triacylglycerol assembly via the Kennedy pathway (*DGAT1*; “pull”), to bring about significant increases in oil content in *B. napus*. This approach holds promise for similar use in other oilseed crops.

Chapter 31 - It is well known that genetic variations can in part affect human oral health. Periodontitis is a common dental noncommunicable disease (NCD). According to the World Health Organization, periodontitis affects 20% of the world population. Periodontal inflammation could eventually induce alveolar bone resorption, causing tooth mobility and tooth loss, which ultimately affects oral function, oral health and the individual’s quality of life. Family study, twins study and linkage analysis in the early years revealed that genetic influence contributes to periodontal disease. Since the first single nucleotide polymorphisms (SNP) study on chronic periodontitis in 1997, many genetic loci were found to be associated with periodontitis, including *IL-1*, *Fc* gamma receptor and complement component 5 genes. Population structure or earlier investigations employing a less desirable sample size may lead to various limitations or bias and therefore diverse results. Meta-analysis reports have proved the association between periodontitis and SNPs in some regions, such as *IL1* and *HLA*. With

development of the technologies, multiple genes can be analyzed in a single assay, and even whole genome SNPs can be screened. Seven genome-wide association studies (GWASs) investigated the potential genetic risk locus for periodontitis and found *GLT6D1* is significantly associated with aggressive periodontitis. In the future, whole genome sequencing, together with replication in multiple populations and functional studies, could potentially disclose the nature of periodontitis as an NCD.

Chapter 32 - Imprinted regions of the mammalian genome are commonly composed of one or more paired paternally and maternally imprinted genes and differentially methylated regions (DMRs). These DMRs are methylated in an allele-specific manner during germ-line or early embryonic development, and they regulate allele-specific gene expression. Although genes in most imprinted regions are expressed ubiquitously among tissues, some imprinted regions manifest tissue-specific gene expression patterns. The brain is a major site of tissue-specific gene expression from imprinted regions in embryonic tissues. The author summarize several imprinted regions that show neuron-specific gene expression patterns. First, the author describe the *SNRPN-UBE3A* domain, which contains three brain-specific imprinted genes, *SNORD115*, *UBE3A-ATS* and *UBE3A*, as well as one imprinted gene with a brain-specific promoter, *SNRPN*. Second, the author discuss the *DLK1-DIO3* domain, which contains the brain-dominant imprinted genes *SNORD112*, *SNORD113* and *SNORD114* as well as numerous brain-specific imprinted miRNAs. Third, the author provide an overview of *Grb10*, which also has a brain-specific promoter and switches the imprinted allele during early neurogenesis. Our chapter reviews these imprinted regions and describes the similarities and differences of the neuron-specific imprinting switch in each region.

Chapter 33 - Treatment of human diseases in general has dual goals: to treat effectively, at the cost of minimal adverse side effects. However, person-to-person differences on drug efficacy and adverse reactions have been frequently observed. Pharmacogenomic studies intend to address such differences based on personal genomic variants such as single nucleotide polymorphisms. In the past, success has been achieved on the identification of major histocompatibility complex genomic variants which are associated to immune-mediated adverse drug effects. Additionally, genomic variants on the direct drug targets have been found to be associated to drug efficacy. Besides immunological and drug-target factors, one other critical factor is on the drug metabolism mediated by various xenobiotic metabolizing and detoxification enzymes. They determine how quickly the drugs can be metabolized and then excreted from the body, thereby affecting drug efficacy and toxicity. Human xenobiotic metabolizing enzymes are categorized by their phases in the metabolizing processes: the modification phase (phase 1), the conjugation phase (phase 2), and further modification and excretion (phase 3). Previously, genes involved in phase 1 have been extensively studied in pharmacogenomics. In comparison, genes in phase 2 received less attention, despite the fact that they are no less important. These genes include Uridine Diphospho-Glucuronosyltransferases and others. This Chapter presents the genomic variants on phase 2 genes which can account for the drug efficacy and adverse reactions.

Chapter 34 - In species with separate sexes, gender differences in longevity are widespread and the extent and direction of these differences varies tremendously among taxa. To understand sexual dimorphism in longevity and explain how different forms of selection shape longevity and other fitness-related traits within and among species, it is important to obtain information on the genetic architecture (the number of genes and degree of inter- and intra-genic interactions) and various mechanistic causes which underlie mortality variation between

the sexes. Here the author review recent empirical studies on gender differences in longevity in insect species, from both mechanistic and evolutionary perspective. Whenever it was possible, the author focus on data obtained from the laboratory evolution experiments because the study of evolution under controlled conditions may provide valuable evidence not only for the effects of natural and sexual selection in shaping sex-specific longevity and mortality rates but also it offers novel insights into the mechanistic basis of these differences.

Chapter 35 - During mating, male bush-crickets transfer a complex spermatophore to the female. The spermatophore is comprised of a large nuptial gift which the female consumes while the sperm from the ejaculate-containing ampulla are transferred into her. Two main functions of the nuptial gift have been proposed: the ejaculate protection hypothesis and the parental investment hypothesis. The former, founded on sexual selection theory, predicts that the time to consume the gift is no longer than necessary to allow for full ejaculate transfer. The latter maintains that gift nutrients increase the fitness or quantity of offspring and hence the gift is likely to be larger than is necessary for complete sperm transfer. With an aim to better understanding the primary function of nuptial gifts, the author examined sperm transfer data from field populations of five *Poecilimon* bush-cricket taxa with varying spermatophore sizes. In the species with the largest spermatophore, the gift was four times larger than necessary to allow for complete sperm transfer and is thus likely to function as paternal investment. Species with medium and small gifts were respectively sufficient and insufficient to allow complete sperm transfer and are likely to represent, to various degrees, ejaculate protection. The author also found that species that produce larger spermatophores transfer greater proportions of available sperm than species producing smaller spermatophores, and thus achieve higher paternal assurance.

Chapter 36 - Mate choice copying was mostly described as a strategy employed by females to assess the quality of potential mates, but also males can copy other males' mate choice. In both cases, focal individuals show an increased propensity to copulate with a potential mating partner they could observe interact sexually with another individual (the 'model'). Sexual interactions, however, convey additional—partly conflicting—information to the choosing individual: females may try to avoid sexually active males due to a rougher courtship or coercive mating attempts, and males may respond to an increased sperm competition risk (SCR). How do females and males respond to different copying situations, in which the model individual either resides in the vicinity of a potential mating partner without physical contact (i.e., no harassment, and low SCR), or interacts sexually with the potential mating partner? Do individuals copy less in the latter situation? The author investigated these questions in the guppy (*Poecilia reticulata*), a livebearing fish with internal fertilization, strong SCR among males, and frequent sexual harassment of females. Focal individuals could choose to associate with a large or a small stimulus fish, and mate choice tests were repeated after the previously non-preferred stimulus fish could be seen associating (low harassment and low SCR) or physically interacting (high harassment and high SCR) with a model individual. In a control treatment, no model was presented. The author found both males and females to copy similarly in both copying treatments, while no response was observed in the control. This contrasts with a study reporting that Atlantic molly (*P. mexicana*) males copy less under elevated SCR. Even though the author lack a compelling explanation as to why both congeners might differ, the author are tempted to argue that strong(er) benefits arising from copying may have selected guppies to copy in a broader range of contexts, including situations where the choosing individual incurs harassment or SCR.

Chapter 37 - Across pre-industrial human societies mating is regulated, with arranged marriage, in which male parents select spouses for their female relatives, being the primary mode of long-term mating. This chapter reviews the model of sexual selection under parental choice that offers a good account for these patterns of human mating. This model postulates that parent-offspring conflict over mating induces parents to control the mate choices of their children, and the spouses they select for them are individuals who conform best to their preferences. By doing so, parents become a significant evolutionary force affecting the course of sexual selection. The model is applied in order to achieve a comprehension of the evolution of specific mating strategies. In particular, it is argued that in a context where mate choice is regulated, at least three mating strategies can thrive: addressing parental choice, addressing female choice and circumventing parental and female choice by force.

Chapter 38 - The need for germplasm banks that safeguard the melon genetic resources is more than justified by the genetic erosion aggravated in the last few decades, not only in the cultivated materials, but also in traditional landraces and wild relatives. The classical and new technologies employed in all stages, from the sample prospecting to resources management, with the conservation and evaluation of the plant resources in between, are described. An added value to these germplasm collections is the use of the genetic resources there preserved in the melon breeding programs. The access to wild genetic resources make possible to exploit them, for instance, for germplasm enhancement incorporating disease resistances in elite varieties. In this sense, conventional breeding methods have rendered unquestionable benefits to agriculture, which can be accelerated by the appearance of new biotechnological tools and genomic resources as a result of the increasing number of vegetable species whose genomes have been or are being sequenced. All germplasm banks, and those preserving vegetable resources like melon in particular, will have to face up to the challenge of characterizing genetically their collections in order to maximize their use in breeding strategies assisted by molecular tools, like molecular markers. At the same time, the use of molecular markers can help to efficiently manage the resources by the creation of core collections. This would alleviate the problems derived from the high number of entries in many of them that is compromising some of the purposes for which they have been created, the conservation and the use of the genetic diversity originally prospected. The advantages in terms of labor and economical investment of preserving, characterizing and using a reduced subset of samples without a considerable sacrifice of the genetic diversity, are undeniable.

Chapter 39 - The evolution of cultivated plants played important role in the ascent of humanity. A large number of theories exist about the evolution of the European grapevine (*Vitis vinifera* ssp. *sativa* L.), it is supposed, that woodland grape itself, or crossing with other species could be the progenitor. The woodland grape (*Vitis vinifera* ssp. *sylvestris* GMEL.) in Hungary is a protected species. The quest and preservation of its populations are significant in terms of nature conservation and reserve of biodiversity as well. In the years of 2010-2015 32 woodland grape genotypes were collected in the Szigetköz, Hungary and ex-situ preserved in the genebank National Agricultural Research and Innovation Centre, Research Institute for Viticulture and Enology, in Badacsonytomaj, Hungary. In 2015-2016 these genotypes were characterised by SSR analysis and were compared with 20 grape rootstocks and 16 *Vitis vinifera* ssp. *sativa* cultivars to ensure the true-to-typeness. Based on the results dendrogram was constructed. In the dendrogram the *Vitis vinifera* ssp. *sylvestris* accessions form an distinct group, but are closer to the *Vitis vinifera* ssp. *sativa* cultivars, than to the rootstocks. This raises the probability, that these accessions are true-to-type woodland grapes.

Chapter 40 - Two major cherry species are grown for their fruit, the diploid sweet cherry and the tetraploid sour cherry. Cherries are characterized by high genetic diversity mainly due to their self-incompatibility propagation system. Estimation of the species phenological and genetic diversity has been performed using a number of different traits and marker systems including morphological and anatomical characteristics, as well as isoenzyme and molecular markers. Different molecular markers have been used, spanning from restriction fragment length polymorphisms (RFLPs) to single nucleotide polymorphisms (SNPs), simple sequence repeat (SSR) markers being the most frequently. Moreover, molecular markers have also been used to mark and trace specific agronomic traits, such as self-(in)compatibility (*S*-alleles) or fruit weight thus developing functional markers. The markers reviewed herein will be useful not only for monitoring the genetic diversity in cherry breeding programs, but also for gene conservation, while these or other markers may permit marker-assisted selection for favorable agronomic traits.

Chapter 41 - Soybean purple seed stain (PSS) causes seed decay and purple seed discoloration, resulting in overall poor seed quality and reduced market grade and value. It is a prevalent soybean disease that also affects seed vigor and stem establishment. PSS is caused by the fungus *Cercospora kikuchii* and other *Cercospora* spp. The most common symptom of this disease occurs on the seed. Infected seeds may appear healthy or have discoloration in seed coat varying from pink to light or dark purple spots with range in sizes from a small speck to the entire seed coat. Warm and humid environments favor pathogen growth and disease development. Management strategies for this disease include crop rotation with non-legume or non-host crops, fungicides applications, and tilling the soil to disrupt spore dissemination. Along with these strategies, the use of resistant cultivars may provide more reliable and economical control of PSS, especially when environmental conditions are conducive for disease development. In this chapter, general information about the PSS and an overview of research on germplasm screening and genetic resistance are presented and discussed.

Chapter 42 - The tissue cryopreservation represents an interesting tool for the conservation of animal biodiversity. The establishment of tissue banks has been indicated as a practical approach to the preservation of species and, associated with other biotechniques, it could provide the rescue or multiplication of endangered species. In general, a large number of wild species have been having their gonadal and somatic tissue cryopreserved and for this purpose, the vitrification is the method routinely used. There is a diversity in cryobiological properties and requirements among cell types within tissues, presenting a challenge for its procedure. Nevertheless, even with those obstacles, studies have shown satisfactory results in many wild mammalian species. The gonadal tissue use involves the possibility for the reestablishment of endocrine functions of the testes and ovary allowing the preservation and posterior use of spermatozoa and/or spermatogonial stem cell and oocytes for other assisted techniques. Recent developments in the autografting and xenografting of testes and ovary clearly demonstrated the potential value of cryopreserving gonadal tissue. Already on the somatic tissue, skin samples have been widely utilized because of the possibility of sampling a large group of animals, without a dependency of limitations regarding gender or age. Moreover, this tissue can be obtained quite easily at using a simple methodology with a reduced cost. In this sense, this chapter highlights the importance of applying tissue cryopreservation to wild mammals conservation at showing the most recent studies in this area and the perspectives for its use in conservative programs.

Chapter 43 - The author sequenced mitochondrial genes (*COI*, *COII*, *Cyt-b*) of accepted Latin America tapir species (*Tapirus pinchaque*, *T. terrestris* and *T. bairdii*) as well as an alleged new species, *T. kabomani*. The mountain tapir (*T. pinchaque*) is a relatively rare large mammal species. Some population censuses indicate that no more than 2,000 mountain tapirs are left in the wilderness areas of Colombia, Ecuador and Peru. Our results showed that the gene diversity levels are medium to low with respect to other mammals sequenced for the same or similar genes. However, these gene diversity levels are not impoverished, which means that the genetic situation of this species is not as critical as its population censuses suggest. It will be crucial to determine the gene diversity levels in certain populations not included in the current work (the eastern and, possibly, western Andean Cordilleras in Colombia as well as the Tabaconas Namballe National Sanctuary in Peru), because they are probably the smallest populations of this species. On the other hand, the lowland tapir (*T. terrestris*), the species with the largest geographical distribution in Latin America, showed the highest gene diversity levels of all the other tapir species studied. Additionally, the genetic structure of *T. terrestris* is clearly more robust than that of *T. pinchaque*. Different geographic populations of both species showed different demographic trends throughout time. Our results including five samples of *T. kabomani* showed this taxon to be a haplogroup within *T. terrestris*, reducing the likelihood of *T. kabomani* being a new full species. Finally, the author also analyzed the influence of diverse Pleistocene climatic changes on the mitochondrial haplotype diversification of *T. terrestris* and *T. pinchaque*. The Pleistocene Refugia and the Recent Lake hypotheses probably played integral roles in the evolutionary history of *T. terrestris*. In contrast, the Pleistocene Refugia hypothesis involving the Andes, which probably played an important part in the genetic diversification of other mammals, did not have a significant impact on *T. pinchaque*.

Chapter 44 - Plants are responsible for a significant part of food supply for the entire world, and through agriculture they play an extremely important socio-economic role for the mankind. Therefore, the development of genetically improved crops becomes even more relevant for it aims at an everlasting enhancement of agronomic traits of interest. For many years, plant genetic improvement program has been based in empiric selection of the target traits; however, significant advances were obtained in the last years. Many tools, allowing crops to be improved with greater optimization of the time needed to reach the necessary modifications, are currently available. Regarding the methods used in the genetic improvement, molecular studies have been essential to identify which genes are important for each specific agronomic trait, such as those related to tolerance to abiotic stress. Such studies contribute not only to a better understanding of the endogenous defense mechanisms of plants at molecular level by which these organisms adapt when facing hostile conditions, but also contribute to the generation of stress-tolerant crops by genetic engineering. These programs aim a significant productivity and sustainability that can be reached through soil preservation that is directly related to less necessity of farm inputs. Better adapted crop cultivars make it possible, as well as better use and decontamination of water resources. In this chapter the author attempt at providing an overview regarding strategies that have been used for prospection of genes related to the response of plants to abiotic stress. The combination of biotechnological and bioinformatics tools used in the identification of stress-related genes and development of genetically engineered crops by silencing and/or over-expression of specific genes will be presented in this chapter. Emphasis will be given to the drought and salinity that represent a major part of abiotic

stresses by which the plants are often exposed, leading to serious production losses in many important crops worldwide.

Chapter 45 - Proteinuria is the hallmark of diabetic nephropathy (DN) and vastly increases the incidence of cardio-vascular disease and mortality. Traditional Chinese Medicine (TCM) has been used for diabetes and its complications for thousands of years and appears to be promising in the treatment of proteinuria in DN patients. Clinical trials evaluating TCM for proteinuria, either used as a monotherapy or in combination with western medicine, has produced positive results. Although a large number of clinical studies have been conducted, the clinical evidence with regard to TCM for proteinuria in patients with DN remains inconclusive. The recent progression of evidence will be introduced in this chapter. Current basic research has disclosed that TCM might affect a variety of genes regarding DN etiology. This chapter will analyze recent achievements in this area and address the issue of the association between clinical evidence and the genetic effects of TCM.

Chapter 46 - Ansamycins are composed of secondary metabolites possessing a high degree of activity against numerous types of Gram-positive and Gram-negative bacteria. Structurally, ansamycins are characterized by the presence of core structures including an aromatic moiety (benzene or naphthalene derivative) and an aliphatic chain. Most ansamycins were isolated and characterized from Actinomycetes, while a few were mined in higher plants, for example, maytansine and colubrinol. Due to the development of microbiological techniques, genetic engineering and recombinant proteins, a wealth of different types of ansamycins have been mined along with their biosynthetic gene clusters. This resulted in developed strategies for enhancement of ansamycin production as well as synthesis of novel structure derivatives. In this chapter, the author will describe the biochemistry and genetics of the most important members of ansamycin antibiotics and their applications as cytotoxic, anti-tumor, anti-parasitic and anti-bacterial agents. Thereafter, the future of ansamycins will be discussed to outline the most critically applied aspects in the last.

Chapter 47 - Ubiquitously expressed protein products of *BRCA1* and *BRCA2* genes are implicated in processes fundamental to all cells, including DNA repair and recombination, checkpoint control of cell cycle, and transcription. *BRCA* gene mutations lead to disruption of *BRCA* proteins in mutation carrier cases and induce susceptibility to specific types of cancer. Among women with germline *BRCA* mutations near 50% of mammary malignancies are triple negative breast cancer (TNBC) presenting with a high grade histologically. Among women with breast cancer, TNBC was established in 57.1% of *BRCA1*-mutation positive and in 23.3% of *BRCA2*-mutation positive cases, whereas in only 13.8% of *BRCA*-proficient women. Although *BRCA* gene mutation carrier women usually exhibit clinical symptoms of defective estrogen receptor (ER) signaling; such as anovulatory infertility and early menopause, the serum estrogen levels of these patients are consequently elevated. In these cases, a compensatory feedback mechanism aims to break through the inherited or acquired ER resistance by increased estrogen synthesis so as to maintain the cellular estrogen surveillance. The higher the estrogen overproduction of *BRCA*-mutation positive cases, the higher the possibility of tumor-free survival. In conclusion, *BRCA1* and *BRCA2* gene mutations seem to increase the breast cancer risk, particularly that of TNBC, in case of insufficient compensation of defective ER signaling. Upregulation of these genes by means of elevated estrogen levels of high parity, artificial hormonal cycle created by oral contraceptives or a pregnancy mimicking high estrogen dose may decrease the excessive cancer risk of *BRCA* mutation positive women.

Chapter 48 - Rett syndrome (RTT) is a neurodevelopmental disorder mainly caused by mutations in the MECP2 gene affecting around 1 in 10,000 female births. Mutations in the MECP2 gene have been associated with the onset of RTT. Clinical manifestations include severe linguistic and motor impairments that are the core of phenotype symptoms. Some patients show a moderate level of conservation of linguistic functions while others lose the use of functional verbal communication. The objectives of the present chapter are to study in depth the latest theoretical approaches to the link between linguistic processes and the specific RTT genotype. This chapter begins with a theoretical overview on cognitive alterations and then focuses on linguistic specific impairments characterized by the loss of articulation or the production of few functional sounds. A restricted sample shows the presence of verbal speech (Preserved Speech Variant). Renieri et al. (2009) proposed the term “Zappella variant” rather than “preserved speech variant” to describe milder forms of RTT, because other aspects, besides speech, are involved. The second part proposes a preliminary research which analyses the correlation between linguistic phenotype and specific genotype.

Chapter 49 - Marfan Syndrome was originally described by Antoine Bernard-Jean Marfan in 1896 and is an uncommon inherited connective tissue abnormality which occurs as an autosomal dominant genetic disorder with frequent mutations. The patients have normal mentation but have a characteristic increase in height, abnormally long limbs, arachnodactyly, joint hypermobility, distinctive facial features, scoliosis, ectopia lentis, dural ectasia and array of aortic and cardiac abnormalities that are often life threatening. The genetic cause of the disease has been identified. Although some medical and surgical treatments are currently in practice they are not always helpful. The orthopaedic problems are often significant and sometimes require complex surgical interventions.

Chapter 50 - Marfan syndrome (MFS) is a systemic connective tissue disorder that is caused by mutations in the extracellular matrix protein fibrillin-1. While MFS is considered to be at high risk of dental disorders and cardiovascular disease (CVD), little causal relationship has been provided to date. In this article, the author reviewed the prevalence of periodontitis in patients with MFS to assess the relationship between periodontal bacterial burden and CVD in MFS patients.

Chapter 51 - Introduction: Pectus deformities can coexist with cardiovascular diseases. This association is well known in tissue conjonctive disorders such as Marfan's syndrom. Combined procedures can be performed safely and represent an interesting alternative in such situations. Valve sparing aortic root replacement has excellent long term outcomes and has become an increasigly popular alternative to aortic root replacement especially in young marfan patients to avoid lifelong anticoagulation. The author present our serie of single-stage pectus correction and cardiac surgery, and emphasize the role of aortic valve sparing interventions in such situations by a review of the literature. Methods: A retrospective review was conducted of patients who underwent chest deformity repair and cardiac surgery at the same time from January 2007 to May 2014. All datas were collected propestively in our data base. A review of literature was conducted to collect all published cases of combined valve sparing root replacement and correction of a chest wall deformity. Results: Including our serie (4 patients) 12 patients underwent a combined Tirone David and chest wall deformity correction. 10 patients underwent a Nuss procedure, 2 patients a modified Ravitch procedure. Conclusion: Combined technique of valve sparing aortic root replacement and correction of a chest wall deformity especially by Nuss technique is safe and effective. This strategy has excellent mid-term results for both aortic and chest wall pathologies.

Chapter 52 - Marfan syndrome frequently causes cardiac complications such as, aneurysm and dilatation of the aortic root. Many Marfan syndrome patients have these cardiovascular problems, and the surgical replacement of aortic and mitral valve, and aortic roots is frequently required. In addition, cases are associated with severe periodontitis, which is a chronic inflammation of the gingiva, periodontal ligament, and alveolar bone. Because of the surgical replacement, it is essential to prevent dental infection, such as infectious endocarditis caused by the periodontitis. In Marfan syndrome, an unfavorable oral hygiene due to the crowded teeth and narrow dental arch had been thought as a cause of severe periodontitis. However, clinical and basic studies have highlighted the genetic background as a pathogenesis of the severe periodontitis. It is suggested that cell alignment and tissue architecture of periodontal ligament are impaired in the model mice of Marfan syndrome. The model mice were more susceptible to alveolar bone resorption after the infection of *Porphyromonas gingivalis*, which is known to cause chronic periodontitis. It is likely that activated TGF- β signaling upregulates IL-17 and TNF- α levels, resulted in the increased alveolar bone resorption. In this review, the perspective of the dental management and the effect of angiotensin II receptor blocker are discussed.

Chapter 53 - Preimplantation genetic diagnosis (PGD) was introduced 24 years ago with the purpose of performing genetic testing before pregnancy, in order to establish only unaffected pregnancies and avoid the need for pregnancy termination, which is the major limitation of traditional prenatal diagnosis. Despite the requirement for ovarian hyperstimulation and in vitro fertilization (IVF), needed to perform genetic testing of oocyte or embryo prior to transfer, PGD has been accepted in most parts of the world. Thousands of PGD cycles have now been performed for single gene disorders, with PGD presently offered for some indications that have never been practiced in prenatal diagnosis, such as late onset diseases with genetic predisposition, and preimplantation HLA typing. The present paper describes our experience on PGD for Marfan syndrome, caused by *FBN1* gene, which was performed in 38 cases, as part of our PGD experience of 2,860 cycles for single gene disorders, which is the world's largest PGD experience.

Chapter 54 - The order Anura currently encompasses over 6,800 amphibian species distributed in 56 families and is an interesting group for cytogenetic studies. Whereas some groups of species present conservative karyotypes, others are highly variable in diploid number or number/location of diverse chromosomal markers, such as nucleolus organizer regions, heterochromatic bands and specific satellite DNA sites. In some cases, karyotypic variation overcomes morphological diversification, turning cytogenetics into a useful tool for taxonomy. Special variation is observed with respect to sex chromosomes and sex determination systems, with both female and male heterogameties observed. Although most species already karyotyped do not show sex chromosome heteromorphism, distinct levels of differentiation are observed between the sex chromosomes of several species, which makes this group particularly interesting for studies of sex chromosome evolution. In this chapter, the author explore the use of cytogenetic data for studies of frogs as well as the insights that hypotheses of phylogenetic relationships have added to this issue. In addition, the author provide a brief review of PcP190 satellite DNA (with new data for the genus *Engystomops*), sex chromosome systems and B chromosomes found in Anura.

Chapter 55 - Humans are daily exposed to a variety of potentially harmful agents in the air they breathe, liquids they drink, food they eat and products they use. Long-standing evidence of the bond between health and environment has led to the recognition for the need of sustainable development. On the other hand, there is an increasing global awareness of the

inevitable limits of individual health care and the need to complement such services with effective public health strategies. According to World Health Organization (WHO), cancer is a leading cause of death worldwide. Additionally, at least 200 000 people die every year from occupational or work-related cancers. Exposure assessment aims at prevention. Establishing the health effects of various activities and exposures requires information about the levels of exposure and the biological effects resulting from the interaction between the organism and the chemical agent. The resulting data provides a basis for designing effective prevention and mitigation strategies. Cytogenetic endpoints have long been applied in surveillance of human genotoxic exposure and early effects of genotoxic carcinogens. Assays measuring chromosomal aberrations (CAs), micronucleus (MN) and sister chromatid exchange (SCE) in lymphocytes are well-established techniques extensively used in human biomonitoring studies to assess DNA damage at the chromosomal level. The relevance of cytogenetic alterations as a cancer risk biomarker is further supported by epidemiologic data linking CAs and MN with cancer risk in human populations. Thus, the use of cytogenetic markers in human biomonitoring is of paramount importance due to its predictability regarding deleterious effects resulting from the exposure to environmental stressors.

Chapter 56 - The great era for classical cytogenetics started sixty years ago with the description of the twenty-three pairs of human chromosomes and the discovery of the Philadelphia chromosome, the first known chromosomal defect associated with a specific type of cancer. Since then many recurrent chromosomal aberrations linked to specific hematological malignancies have been detected. The vast majority of these abnormalities can be detected by modern molecular genetic methods so it might seem there is no longer a need for microscopy. However, there is still a significant portion of hemato-oncologic patients for which the classical cytogenetic investigation is appropriate, i.e., cases with complex karyotypes. Complex karyotypes are characterized by the presence of three or more unrelated chromosomal aberrations co-existing in a single clone. Their occurrence is associated with adverse outcomes across the entire spectrum of hematologic malignancies. These aberrations are also a powerful diagnostic indicator for molecular targeted therapies, allogeneic stem cell transplantation or other generally more aggressive treatment strategies. Since the presence of complex karyotypes would be missed when using only molecular genetic methods, this highlights the irreplaceable role of classical cytogenetics as a first-tier analysis for the evaluation of complex structural chromosomal abnormalities in hemato-oncologic patients. Ideally, classical cytogenetics is then followed by more precise molecular genetic methods to identify specific chromosomal aberrations more deeply. Here the author focus on the complex karyotype issues in the myelodysplastic diseases, leukemias, lymphomas and multiple myelomas as seen daily in our center.

Chapter 57 - Initially identified as *Astyanax schubarti* on the basis of morphological characteristics, its chromosomal analysis revealed a unique diploid number in the genus. With 42 chromosomes and the impossibility of homologous pairing, the karyotype of the individual was compared to a set of haploid complements of *Astyanax schubarti* ($2n = 36$ chromosomes) and *Astyanax fasciatus* ($2n = 48$ chromosomes). Natural hybrids are rare. The viability of a hybrid between species with such chromosomal discrepancy may offer important hypotheses to explain the morphological, molecular, and cytogenetic diversity of the genus.

Chapter 58 - There are three distinct subtypes of Trichorhinophalangeal syndrome (TRPS); TRPS type I, TRPS type II and TRPS type III. Features common to all three subtypes include sparse, slowly growing scalp hair, laterally sparse eyebrows, a bulbous tip of the nose (pear-

shaped), and protruding ears. The diagnosis of TRPS is based in typical clinical and radiographic features, as well as in the identification of causative mutations in the *TRPS1* gene (TRPS type I and III) and in loss of functional copies of the *TRPS1* and *EXT1* genes (TRPS type II). The mode of inheritance in TRPS I and III is autosomal dominant, however *de novo* deletions of *TRPS1* and *EXT1* genes are the main defect of TRPS II. Parental balanced chromosomal rearrangements are an important cause of interstitial aberrations in TRPS. In cases of cytogenetically-invisible alterations, parental FISH analysis as well as aCGH should be considered as part of the clinical baseline testing. Treatment of clinical problems of TRPS types is mainly supportive and includes ectodermal and skeletal issues. The number of distinct syndromes as TRPS is rapidly increasing and their confirmation is necessary especially in cases that typical features are absent. Clinical geneticists should provide information for the families and advise them how to overcome problems.

Chapter 59 - It is generally believed that genotype and adult lifestyle elements are primary risks of some metabolic diseases such as insulin resistance, obesity and diabetes mellitus in later life. However, increasing evidence demonstrates that early life malnutrition during the period of gestation and/or lactation may increase our susceptibility to such metabolic diseases in later life. The underlying mechanism is still not very clear. Recently, epigenetics is hypothesized to be the important molecular basis of the imbalanced early life nutrition and glucose metabolism disorders, which is known as "Developmental Origin of Health and Diseases" (DOHaD). Currently, there are substantial epidemiological studies and experimental animal models that have demonstrated nutritional disturbances during the critical periods of early life development can significantly impact the predisposition to developing some metabolic diseases in later life. The fundamental mechanism is that early developmental nutrition can regulate epigenetic modifications of some genes associated with development and metabolism. DNA methylation is the first discovered and one important epigenetic modification. MicroRNAs are recognized as an important epigenetic modification and they are a major class of small non-coding RNAs (about 20-22 nucleotides) which can mediate posttranscriptional regulation of target genes with cell differentiation and apoptosis. Recent studies suggest that DNA methylation and microRNAs maybe the crucial modulators of fetal epigenetic programming in nutrition and metabolic disorders. This chapter will focus on how early life nutrition can alter the epigenome, produce different phenotypes and alter disease susceptibilities, especially for impaired glucose metabolism.

Chapter 60 - Oxidative stress is a state in which production of reactive oxygen species exceeds the capacity of antioxidant systems. Reactive oxygen species have one or more unpaired electrons, making them highly reactive with other cellular molecules such as protein, lipid, and nucleic acid. The peroxidation of polyunsaturated fatty acids in biological membranes results in impaired membrane integrity. Oxidatively modified proteins lose *their* capacity to carry out the *physiological functions* and they may form intracellular aggregates. Attacks of reactive oxygen species to DNA results in strand breakages and base oxidation. Major DNA oxidation product is 8-hydroxydeoxyguanosine which has a pro-mutagenic potential. Due to these damaging effects, oxidative stress plays an important role in various pathologies such as cancer, diabetes, chronic inflammatory diseases and neurodegenerative disorders. Epigenetic changes are regular and natural events which regulate gene expression without changing base sequences on DNA. Dysregulation of regular epigenetic mechanisms is a contributory factor for many of human pathologies. Recently, reactive oxygen species have been shown to cause epigenetic dysregulations that play a pivotal role in human disorders. The basic epigenetic

mechanisms and their dysregulation by reactive oxygen species have been reviewed in this chapter.

Chapter 61 - Cancer is one of the deadliest malignancies that have plagued mankind for decades. Epigenetic mechanism(s) play a central role in the homeostasis of normal cell proliferation and differentiation. Global epigenetic modifications are frequently associated with cancer initiation, progression, as well as metastasis. These changes include DNA methylation, histone lysine methylation/demethylation, acetylation/ deacetylation, including methylation and acetylation of non-histone proteins, and can alter the expression of various oncogenic signaling cascades, which in-turn can lead to uncontrolled proliferation. In this chapter, the author primarily focus on the major epigenetic changes that occur in oncogenes, tumor suppressor genes, transcription factors and cancer stem cells, which in turn mediate tumor growth. These modifications are controlled by regulatory enzymes such as DNA methyltransferase, histone acetyltransferases, histone deacetylase, lysine acetyltransferase, and arginine and lysine methyl transferases. In addition, the author also describe a few selected pharmacological agents that can modulate the action of these enzymes and display significant potential for cancer therapy.

Chapter 62 - Alzheimer's Disease is one of the most common neurodegenerative disorders. Many efforts have been directed to prevent AD due to its rising prevalence and the lack of an effective curative treatment. Epigenetic changes are involved in regulation of gene expression, and may mediate various pathologies. Epigenetic changes are reversible so that can be easily modulated. Modulation of dysregulated epigenetic mechanisms is a promising therapeutic approach for many diseases. There is some evidence for epigenetic dysregulation at various levels contributing to AD pathogenesis. Despite the recent rapid accumulation of knowledge about AD pathogenesis, the role of epigenetic modifications has not been understood exactly. This chapter provides a brief overview about the role of epigenetic changes that are linked to AD pathogenesis and emerging targets for new therapeutic strategies in this field.

Chapter 63 - Cardiovascular disease (CVD) is not a single condition, but an umbrella term used to describe a range of common diseases affecting the heart and the circulatory system. The term commonly includes diseases of the cardiac muscle and of the vascular system supplying the heart, brain, and other vital organs. Many of these conditions can be life-threatening. CVD is the leading cause of death in the world, affecting all populations, irrespective of demographic or socioeconomic differences and is responsible for one third of all deaths. In the present chapter, the author focus on the epigenetic control of embryonic cardiac development and the role of epigenetic mechanisms in CVD observed from results in human, animal and cell culture studies' approaches. The author discuss the main epigenetic mechanisms involved in heart development and major CVDs such as coronary heart disease (CHD), heart failure (HF), myocardial infarction (MI), hypertension, stroke, arrhythmias, cardiomyopathy and cardiac hypertrophy (CH). Additionally, this chapter also focuses on the epigenetic modifiers that are involved in the development of CVD, and the potential utility of epigenetics-based therapeutic strategies in CVD.

Chapter 64 - Extensive characterization has been performed on the genes and genetic mutations that are involved in spermatogenesis and male infertility, but the vast role of the sperm's transcriptome and epigenome in male reproduction has yet to be completely explored. Recent research has established that epigenetic remodeling of the sperm is necessary for development and for its function following fertilization. The histone- retained regions of the sperm have been recently shown to carry the bivalent marks of activating histone H3 lysine K4

trimethylation and the repressive H3 lysine K27 trimethylation. These bivalent histone marks facilitate the dynamic changes in stage-specific gene expression during sperm development. The paternal epigenome bears unique and important epigenetic modifications determined to be potentially important to the developing embryo, but the complete scope of its contribution is still emerging. Additionally, advances in assisted reproductive techniques have also suggested that alterations in the epigenetic profile in infertile men are transmitted to the developing embryo. This review will highlight the latest advances in epigenome profiling of the chromatin modifications during the development of immature to a mature sperm as well as provide a glimpse into the future role of epigenetic mechanisms in the generation of new germ cells/gametes from induced pluripotent stem cells, to treat male infertility.

Chapter 65 - Epigenetic is defined as the study of mitotically and/or meiotically heritable changes in the gene function without changing DNA sequence and playing crucial roles both in normal development and human diseases. The molecular basis of epigenetic process consists of histone modifications, DNA methylation, positioning of histone variants, and non-coding RNAs. Genome-wide patterns of DNA and chromatin modifications together called as 'epigenomes'. Epigenomes undergo precise, coordinated, reversible changes through the developmental stages and so contributes to the lineage and tissue specific expression of genes. In addition to the tissue specific impact, environmental factors such as nutrients, toxins, infections and hypoxia can also influence epigenomes. Distinct or global changes in the epigenetic landscape are hallmarks of chronic inflammation associated diseases. Alteration in methylation status of CpG sites, monoallelic silencing, and other epigenetic regulatory mechanisms have been observed in key inflammatory response genes. Epigenetic changes including DNA methylation, histone modification and noncoding RNA expression, were found associated with acute and chronic inflammatory disorders. Recently, therapies targeting epigenetic mechanisms are trending options for the treatment of chronic and degenerative disorders. Epigenetic drugs that are applied on animal models and some clinical trials are displaying positive therapeutic effects. Not only mono therapies but also combined usage of HDAC or DNMT inhibitors could be the next step for the epigenetic therapeutic modulations. Scope of this chapter is to provide an overview of the epigenetic modifications in inflammation and inflammation driven diseases.

Chapter 66 - Obesity is a public health problem leading to morbidity and mortality throughout the world. It arises from the interactions between genetics and environmental factors. In recent years, susceptibility to obesity has been also linked to epigenetic factors. Epigenetics, is the study of heritable changes in gene expression which do not involve in the underlying DNA sequence. The epigenetic mechanisms include DNA methylation, covalent histone modifications, chromatin folding, miRNAs, and polycomb group repressive complexes. Both dietary factors and individual behaviors affect obesity development via epigenetic mechanisms. Epigenetic mechanisms are also linked to programmed changes in gene expression as a result of early environmental exposures during pregnancy which alter offspring growth and development. There is evidence that nutrient and environmental exposures during pregnancy may affect fetal/newborn development and result in offspring obesity or metabolic syndrome which is a cluster of metabolic abnormalities. Obesity related genes, epiobesigenes, display methylation patterns playing important roles in the development of obesity which are potential future epigenetic biomarkers of obesity. The susceptibility genes have been reported as FGF2, PTEN, CDKN1A, and ESR1, functional in adipogenesis; SOCS1 and SOCS3, functional in inflammation, and COX7A1, LPL, CAV1, and IGFBP3 which are functional in

fat metabolism and insulin signaling. It is important to prevent this era's epidemic, obesity, since it leads to chronic diseases including hypertension, atherosclerosis, insulin resistance, and moreover metabolic syndrome. It may be easier to prevent the progress of the disease by revealing the epigenetic mechanisms especially methylation profiles of the susceptibility genes.

Chapter 67 - Entomopathogenic fungi have been mentioned as one of the best alternatives for insect pest control. These fungi cause insects death. More than 750 fungal species have been described infecting insects, some of the most utilized for insect control are: *Beauveria bassiana* and *Metarhizium anisopliae*. This is evidence of cosmopolitan distribution of entomopathogenic fungi and its evolutionary success, this type of fungi is related to a serie of interactions among fungi, plants, and insects. In this chapter, the main objective is to review and discuss the most recent information on genetics and evolution of entomopathogenic fungi. In this chapter are covered the following themes: Entomopathogens role in nature, Entomopathogenic fungi and their interactions with the insect immune system, Isolation and identification of entomopathogenic fungi, Genetic diversity among strains of entomopathogenic fungus, Genes involved in virulence of entomopathogenic fungi, Molecular phylogeny of entomopathogenic fungi and their biogeographic implications, Evolution of entomopathogenicity in fungi, Genetic improvement of entomopathogenic fungi for insect biocontrol, Future trends and Conclusions.

Chapter 68 - The author sequenced the mitochondrial (mt) *ND5* gene of 100 specimens of *Eira barbara* (Mustelidae, Carnivora). The samples represented six out of the seven putative morphological subspecies recognized for this Mustelidae species (*E. b. inserta*, *E. b. sinuensis*, *E. b. poliocephala*, *E. b. peruana*, *E. b. madeirensis*, and *E. b. barbara*) throughout Panama, Colombia, Venezuela, French Guiana, Brazil, Ecuador, Peru, Bolivia, Paraguay, and Argentina. The main results show that the genetic diversity levels for the overall samples and within each one of the aforementioned putative taxa were very high. The phylogenetic analyses showed that the ancestor of the Central and South-American *E. barbara* originated during the Miocene or Pliocene (6.3-4 millions of years ago, MYA). Furthermore, the ancestors of some geographical groups, (we detected at least four) originated during the Pliocene (3.7-2.5 MYA). These four groups (or lineages) were placed in the Cesar-Antioquia Departments (northern Colombia), Bolivia and northwestern Argentina, northern-central Peru, and in the trans-Andean area of Ecuador. However, during the Pleistocene, this species experienced a strong population expansion and many haplotypes expanded their geographical distributions. They became superimposed on the geographical areas of older geographical groups that originally differentiated during the Pliocene. Until new molecular studies are completed, including those with nuclear markers, the author proposed the existence of only two subspecies of *E. barbara* (*E. b. inserta* in southern Central America, and *E. b. barbara* for all South America). All of the demographic analyses showed a very strong population expansion for this species in the last 400,000 YA during the Pleistocene.

Chapter 69 - Like other forms of diagnostics, genetic testing comes with a retinue of costs and benefits. Significant benefits in terms of morbidity and mortality have accrued to individuals tested for more prevalent genetic conditions like cystic fibrosis and sickle cell disease, including persons seen in the emergency room or identified through public health surveillance. These benefits do not mitigate the drawbacks of genetic testing, false and missed diagnoses and sheer cost among them. Both medicine and public health have aimed at means of maximizing genetic test benefits in the interventions that they apply. The President's Precision Medicine Initiative (PMI) holds promise in that its results could be used to tailor

medical treatments to the individual characteristics of patients, “precision” implying a more accurate and precise regimen overall. The National Cancer Institute (NCI) has already launched the NCI-MATCH precision medicine trial, which assigns targeted treatments based on the genetic abnormalities in a tumor, regardless of cancer type. Other trials, such as the NCI Pediatric MATCH trial, are yet to happen. The efficacy of cancer treatments also intersects public health concerns. The Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Working Group has evaluated the use of *UGT1A1* genotyping to determine the best dose of irinotecan to prevent side effects when treating patients for metastatic colorectal cancer. Analytic validity does not always equate with improved patient outcomes, however, thus the public health emphasis on development of a suitable evidence base for precision medical and public health efforts. The public health approach to precision medicine, or “precision public health”, differs from the medical approach in several important ways: (1) population-based with attention to at-risk populations, as opposed to being strictly individualized; (2) focus on primary and secondary prevention, rather than frank disease (tertiary prevention); and (3) prioritizing interventions that have already demonstrated readiness for large-scale implementation, in contrast to the undertaking of novel clinical trials. Precision public health is exemplified in the Centers for Disease Control and Prevention’s emphasis on the implementation of Tier 1 genetic tests that have passed systematic review for analytic and clinical validity and utility – the use of family history for referral for hereditary breast and ovarian cancer genetic testing (*BRCA1/2* mutations), and hereditary nonpolyposis colorectal cancer cascade screening (Lynch syndrome *MLH1*, *MSH2*, *MSH6* mutations). This paper will cross-compare the precision medical approach to cancer based on pharmacogenomic regimens using companion diagnostics, and the public health approach to precision management of hereditary cancer for 3 cancer types – lung, breast, and colorectal. It will describe methods of early detection and consider how lives can be saved through precise management – from predictive testing and cancer monitoring of the at-risk population, to tailored chemoprevention that fits the needs of the individual. In the population context, a cascade screening “multiplier effect” exists in that relatives can also be assessed and followed for mutations identified in the proband. Cost-benefit analyses (T4 translational research) of medical and public health approaches will be closely examined and compared. Points of commonality between the two approaches will also be discussed, since primary/secondary and tertiary disease prevention represent a continuum. These analyses point to the value of allocating resources towards the health of at-risk populations. Questions remain if particular forms of genetic testing are to become “universalized”, and if the needs of all at-risk groups, including racial-ethnic, are to be addressed.

Chapter 70 - Williams syndrome (WS) is a genetic neurodevelopmental disorder (prevalence close to 1 in 20,000-30,000 births) resulting from the deletion of 16-25 genes on the long arm of Chromosome 7. Individuals with WS have an intelligence quotient of 40-70. Theirs is a unique neuropsychological profile, characterized by an apparent dissociation between cognition and language, as language is relatively well preserved, compared with other cognitive skills. However, a more complex profile is now emerging, with good lexical, short-term memory (especially auditory-verbal) and face processing skills, but visuospatial (especially local processing of information), executive (planning and inhibition), memory (working memory and long-term) and attentional deficits. Individuals with WS also have specific auditory-perceptual cognitive skills (hyperacusis), category-specific perception of speech sounds, and musical skills that exceed their cognitive level. Other behavioral characteristics include hypersociability. In this chapter, the author provide a review of the

literature on the specific neuropsychological profile of individuals with WS, from a cognitive-behavioral and neuroanatomical point of view. Early studies of the neuropsychological profile in WS focused on the dissociation between cognition and language. Since then, research has shown this syndrome to be more complex. Our aim is to highlight the heterogeneity of the cognitive profiles observed in this syndrome, and to identify the factors that might explain this heterogeneity. The complexity and specific features of the neuropsychological profile in WS need to be understood in order to develop therapeutic and learning methods adapted to the developmental pace of individuals with WS.

Chapter 71 - Chromosome rearrangements are the most common genetic abnormalities in humans. Abnormal chromosomal configurations are formed among non-homologous chromosomes to allow full synapsis of homologous chromosomes at meiosis I of chromosome rearrangement carriers. These abnormal chromosomal configurations result in the production of gametes with various chromosomal complements due to malsegregation of derivative chromosomes or recombination. Most of the gametes have unbalanced chromosomal complements and only a small number of gametes have normal or balanced chromosomal complements. Carriers of balanced chromosome rearrangements are phenotypically normal but they are at an increased risk of abnormal pregnancies due to the unbalanced gametes. However, chromosome rearrangement carriers who cannot have babies or experience repeated abortions or abnormal pregnancies can have healthy babies after introduction of PGD. Balanced reciprocal translocation is the most common chromosome rearrangement. Thirty-two types of gametes can be produced in meiosis of reciprocal translocation carrier. According to the results that analyze the meiotic segregation of embryos from PGD cycles of reciprocal translocation carriers, 2:2 segregation is the main segregation mode. The meiotic segregation might be affected by the gender of carriers. The frequency of balanced embryos was not different between female and male carriers. However, the frequencies of 2:2 segregation, especially adjacent-1 segregation, 3:1 and 4:0 segregation were significantly different between female and male carriers. Robertsonian translocation is also common chromosome rearrangement in humans. Gametes with eight different chromosomal complements can be produced in Robertsonian translocation carriers. The frequency of balanced embryos was higher in male carriers than in female carriers. Carriers of complex chromosome rearrangements (CCR), very rare chromosome rearrangements, can achieve pregnancy by PGD although the number of normal or balanced embryos was extremely low. Although it is very difficult to estimate the rate of normal or balanced embryos, the rate is estimated to be less than 10% in PGD for CCR carriers. The 3:3 segregation and chaotic segregation (meiotic segregation whose meiotic segregation cannot be defined) are prevalent segregation modes in carriers of three-way translocation. In PGD cycles of CCR carriers, cycle cancellation is very frequent due to the absence of the normal or balanced embryos. Therefore, it is important that a large number of embryos are obtained in one cycle. Occasionally, abnormalities of chromosome rearrangement-unrelated chromosomes are observed in embryos or abortuses although chromosome rearrangement-related chromosomes are normal or balanced. At present, PGD that diagnose all 24 chromosomes using array-CGH, SNP array or NGS is carried out worldwide. In those PGD cycles, the risk that embryo transfer is cancelled might be increased. However, the rate of normal or balanced embryos is unexpectedly increased and pregnancy rate is improved. Surely, PGD is the very effective assisted reproductive technique in achieving pregnancy of chromosome rearrangement carriers by preventing repeated abortions that chromosome rearrangement carriers usually experience. In the field of PGD for chromosome

rearrangements, the next stage will be the development of technique that can discriminate between normal embryos and balanced embryos. Chromosome rearrangements, such as translocation (reciprocal or Robertsonian), inversion and complex chromosome rearrangements, are the most common genetic abnormalities in humans. Chromosome rearrangements are classified as balanced or unbalanced. Carriers of balanced chromosome rearrangements have the normal chromosomal complements but carriers of unbalanced chromosome rearrangements have additional or missing chromosomal material. Generally, the incidence of balanced chromosome rearrangements is about 0.19% of newborns. Carriers of balanced chromosome rearrangements are phenotypically normal because they have all the genetic materials. However, they are at an increased risk of implantation failure, repeated abortions or birth of chromosomally unbalanced offspring. Of course, not all carriers of balanced chromosome rearrangements experience the abnormal pregnancies. The abnormal pregnancies are resulted from the unbalanced gametes generated during meiosis of chromosome rearrangement carriers. Abnormal chromosomal configurations are formed to allow full synapses of homologous chromosomes during meiosis of balanced chromosome rearrangement carriers. The unbalanced gametes are produced as a results of malsegregation of these abnormal chromosomal configuration. Most of the gametes produced during meiosis of chromosome rearrangement carriers have unbalanced chromosomal complements. These unbalanced gametes result in implantation failure, repeated abortions or birth of chromosomally unbalanced offspring. After the first successful clinical application of preimplantation genetic diagnosis (PGD) in 1990, PGD has been widely used worldwide to select normal or balanced embryos in *in vitro* fertilization and embryo transfer (IVF-ET) programs of balanced chromosome rearrangement carriers. Cleavage-stage fluorescence in situ hybridization (FISH) has been widely used to PGD for carriers of balanced chromosome rearrangements till the early 2010s and PGD based on array comparative genomic hybridization (CGH) or next generation sequencing (NGS) is widely applied nowadays. The only abnormalities of rearranged chromosomes can be diagnosed in FISH-based PGD and the abnormalities of other chromosomes cannot be diagnosed. However, abnormalities of all 24 chromosomes can be diagnosed after the application of array CGH or NGS into PGD.

Chapter 72 - *Aims*: Attention deficit hyperactivity disorder (ADHD) is a multifactorial psychiatric and neurobehavioral disorder. The brain-derived neurotrophic factor gene (*BDNF*) has been proposed as a strong candidate for this pathology. The aim of this study was to determine a family-based association between three polymorphisms of the *BDNF* gene and the ADHD in a Tabascan-Mexican population. *Methods*: The author analyzed the rs6265, rs12273363 and rs11030119 polymorphism of the *BDNF* gene through a family-based association study. A total of 105 individuals grouped in family-trios (mother, father and ADHD patient) were studied. Allelic and haplotypic transmission were assessed through transmission disequilibrium test (TDT), using HaploView software. *Results*: No statistically significant association was observed between the *BDNF* gene polymorphisms and the ADHD etiology in Tabascan-Mexican families: rs6265 ($\chi^2 = 1.33$; $p = 0.24$); rs12273363 ($\chi^2 = 1.33$; $p = 0.24$); rs11030119 ($\chi^2 = 0.66$; $p = 0.41$). Furthermore, no preference of transmission was observed for any of the haplotypes. *Conclusions*: It was not possible to prove any association between the *BDNF* gene polymorphic variants and ADHD in a Mexican population. Future studies comprising larger samples are necessary to determine the potential role of the *BDNF* gene in ADHD.

Chapter 73 - Petroleum can be characterized as an oily, flammable substance, less dense than water, with a distinctive scent and color ranging from black to dark brown. The petroleum industry includes some global processes that can be highlighted by the environmental risks they present. At offshore platforms, the danger of a spill is aggravated by the density of the oil, which floats and is carried quickly through sea currents. Thus, in addition to the marine fauna, coastal fauna and flora (e.g., mangroves and estuaries) can also be affected by a leakage. Petroleum is predominantly composed of hydrocarbons, these can be degraded by several species of bacteria, which are of great interest for the bioremediation of contaminated environments. Among these species the author can mention *Pseudomonas*, *Sphingomonas*, *Mycobacterium*, *Microbacterium* and *Gordonia*. The success of a bioremediation process depends on numerous factors such as microbial biomass, population diversity, enzymatic activity, pH, temperature, and carbon source. Moreover, the strains have their genetic potential for bioremediation investigated through methods of analysis concerning genes related to the degradation of aliphatic and aromatic hydrocarbons mostly by oxygenases, such as the polycyclic aromatic hydrocarbon ring-hydroxylating dioxygenases (PAH-RHD_o), and *alkB* (for n-alkane degradation) genes. The study of autochthonous microbial communities is of crucial importance for the understanding of the genetic and biotechnological potential of bioremediation in environments close to the areas of extraction and susceptible of contamination; it is also of great interest for industry and biotechnological development. This chapter covers the main aspects of petroleum, regarding its exploitation aspects, the process of geological formation, and environmental impacts. It will include topics in microbiology and genetics; for instance, metabolic pathways of hydrocarbon biodegradation, biofilm dynamics associated to the oil industry, metagenomics of communities in marine environments, corrosion influenced by microorganisms (CIM), microbial control methods related to the petroleum industry, and bioremediation will be discussed.

Chapter 74 - In healthy individuals, the incessant activity of regulatory genetic mechanisms ensures the metabolic and proliferative equilibrium of cellular activity. In case of accidental defects occurring in any part of the system, a coordinated counteraction of numerous mediators may successfully help in the restoration of physiologic processes by means of either overexpression or hyperactivity. Even serious defects of genome stabilizer mechanisms may be kept in balance for a long duration, showing the clinical signs of good health. By contrast, due to the exhaustion of the compensatory processes, DNA defects may develop and lead to the clinical manifestations of diseases. Estrogen activated estrogen receptors (ERs) are the primary initiators and organizers of the up-regulatory circle of genome stabilization in correlation and crosstalk with aromatase enzyme and genome safeguarding proteins, such as BRCA_s. The promoter regions of *ESR1*, *BRCA1*, and *CYP19* aromatase genes exhibit strong triangular partnership for the harmonized regulation of the synthesis of ERs, BRCA proteins and aromatase enzyme, which can be reconstructed from the meticulous details of earlier scientific results. Considering the extreme capacities of ER-signaling for self-restoration, it is obvious that antiestrogen treatment, either ER binding by a false ligand or inhibition of estrogen synthesis, may provoke extreme compensatory actions in genetically proficient cases. Analyses of the results of genetic studies on tumor cells have shown that upregulation of ER-signaling induced by natural estrogen or antiestrogen is a beneficial defensive process even in tumor cells, promoting their domestication and elimination. A schematic representation of the main stream of upregulative genome stabilizing circle visualizes the possibilities for extreme counteractions against the toxic effects of antiestrogens. The presented complex genome

stabilizer mechanisms reveal that cancer cells may preserve their residual capacity for the upregulation of ER-signaling, even if the efforts are not satisfactory.

Chapter 75 - Rett syndrome (RTT) is a rare, neurodevelopmental genetic disorder that develops in early childhood and influences many functions within neurobehavioural domains. The core of phenotype symptoms includes severe linguistic and motor impairments. The onset of RTT is characterised by a gradual or sudden loss of speech and hand function followed by a slow decrease in acquired gross motor skills with subsequent severe functional dependence. RTT is associated primarily with mutations in MECP2, a gene located on the long arm of the X chromosome (Xq28). The severity of impairments depends not only on genotype, but on the extent of X inactivation. However, CDKL5 and FOXP1 gene mutations have been also identified in girls affected by atypical RTT. Despite sharing neurological features, subjects with RTT present considerable clinical variability. Research on effects of genotype of RTT is expanding in many directions. The current chapter, will discuss the correlations between genotype and motor abilities in subjects with RTT. The main aim of this chapter is to relate functional outcomes, in particular motor impairments, to mutation type in patients with RTT. This chapter begins with a theoretical overview on genetic alterations in RTT and then focuses on motor specific impairments. In the second part of this chapter, the author propose a preliminary research which analyzes the correlation between motor phenotype and specific genotype.

Chapter 76 - Fragile X syndrome (FXS) is the most common inherited cause of intellectual disability. However, findings reported in cross-sectional studies on this population are heterogeneous. This chapter focuses on the longitudinal assessment of a boy with FXS from 12 months through to 6 years of age using two tests: one that assesses psychomotor development and another that assesses neuropsychological maturity. The child had attended an Early Childhood Development Intervention Center-ECDIC since 12 months old. He was administered the *Brunet-Lézine Revised Scale of Psychomotor Development in Early Childhood* until 36 months and underwent CUMANIN neuropsychological testing from age 3 to 6. The results obtained allow us to observe trends in the boy's psychomotor development and neuropsychological maturity over time. Significant commonalities between these results and those of previous cross-sectional studies are discussed. Furthermore, some conclusions are drawn that may prove valuable to professionals and researchers interested in this syndrome.

Chapter 77 - Cornelia de Lange syndrome (CdLS), also known as Bushy syndrome, Amsterdam dwarfism and Brachmann- de Lange syndrome is a genetic multi system disorder, usually caused by spontaneous mutation. Although present from birth, it may not always be immediately diagnosed. The estimated incidence is about 1:10,000-30,000 births. Both sexes are affected. Mortality is high early in life and neurosensory, craniofacial, musculoskeletal, cardiac and gastrointestinal abnormalities are all apparent. There is no known cure and treatment is supportive, requiring a team support system.

Chapter 78 - *Background:* SCAs are the most frequently occurring chromosomal abnormalities with an incidence of 1 in 400 births. As the number of X chromosomes increases, the phenotypic severity increases as well and it is estimated that cognitive abilities decrease by 10–15 IQ points for each additional X chromosome. Aim of this paper is to illustrate clinical variability of cognitive-behavioral phenotype in the different SCAs. *Design and Methods:* The sample was composed by 53 subjects (mean age = 21.16 yrs, range: 13-54) with karyotype 47, XXY (73%), 49, XXXXY (7%), 48, XXYY (9%), mosaicism 47, XXY/48, XXXY (2%), 47, XYY (5%), 48, XXXY (2%), 49, XXXYY (2%). Only 5 subjects have been diagnosed

prenatally (4 KS and 1 XXYY). Primary caregivers completed a comprehensive questionnaire detailing birth, medical, developmental and psychological history. Cognitive and behavioral assessment was performed with clinical interviews using DSM 5 criteria and psychometric questionnaires (WISC-R, WAIS-R, CPM, Token Test, VABS, SCL90, SCQ). Twenty-one sex and age matched subjects karyotypically normal were also evaluated from the behavioural point of view. *Results:* Mean IQ in typical KS was 87.45 ± 2 ds (sd = 20.12) range 45-123, VIQ 91.74 (sd = 19.55) range 50-130 and PIQ 86.87 (sd = 20.87) range 50-126. Mean IQ in other SCAs was 68.71 (sd = 20.81) range 45-106, VIQ 69.36 (sd = 21.97) range 47-113 and PIQ 74.72 (sd = 21.70) range 45-112. In CPM KS subjects scored 27.75 (range 13-36) and 31.50 in the Token Test (range 21-35) while in CPM the other SCAs subjects scored 22.27 (range 10-35) and 22.50 (range 9-31) in the Token Test ($p < .05$). VABS scores documented more marked impairment on adaptive behavior in atypical SCAs subjects. SCL90 documented an elevation of paranoid scale in the 70% of KS subjects and 50% of other SCAs. Autistic traits were present in 67% of the other SCAs subjects and in the 18% of KS at the SCQ. *Conclusion:* A precise identification of the cognitive and behavioral phenotype in different SCAs may enhance the clinical treatment, anticipatory guidance, and care throughout the lifespan.

Chapter 79 - Transcranial direct current stimulation (tDCS) is a non-invasive, painless brain stimulation treatment that uses direct electrical currents of low intensity to stimulate specific parts of the brain. tDCS could both facilitate (anodic stimulation) and inhibit (catodic stimulation) specific areas of the brain, as many neurological and psychiatric disorders are linked to a hypofunction or hyperfunction of specific areas of the nervous system. Such phenomenon is based on two processes: rearrangement of functional neural circuits, and their reconstruction. In light of the studies mentioned above, it is assumed that tDCS can represent a useful tool to facilitate the process of neuroplasticity in subjects affected by chronic neurological diseases and genetic etiopathogenesis, such as Rett Syndrome (RTT). The aim of the present study is to examine the neurophysiological and cognitive effects of cognitive empowerment combined with tDCS in young girls and women with RTT, with chronic language impairments. Despite results in cognitive rehabilitation showing a positive trend, the efficacy of specific intervention on articulated speech is less consolidated. Lack of current research on successful outcomes in language production prompted the current study, which focuses more on intervention of articulated speech and cognitive functions. In this chapter, the author propose an integrated intervention: tDCS and cognitive empowerment applied to language in order to boost speech production (new functional sounds and new words). Given that maximal gains are usually achieved when tDCS is coupled with behavioural training, the author applied tDCS stimulation on Broca's area together with linguistic training. Fourteen young girls and women with RTT were randomly allocated into two subgroups: AtDCS ($n = 7$) or placebo tDCS ($n = 7$). tDCS was applied over Broca's area for a 20-minute session for ten consecutive days. During tDCS stimulation, speech rehabilitation was divided into two sessions: production of vowels and word associations, and discrimination between corresponding words and images. Neurophysiological and cognitive parameters were measured at baseline, post-training and one month after intervention. Results show a general enhancement in language, motor coordination and neurophysiological parameters in the AtDCS group compared to the placebo group. The present study provides evidence that tDCS combined with cognitive empowerment can improve language abilities and motor coordination and foster brain plasticity in young girls and women with RTT. Hence, this study supports the role of tDCS

stimulation as a new methodology in the rehabilitation of diseases with chronic impairment and genetic etiopathogenesis.

Chapter 80 - The present study examined the control of force and timing during finger tapping sequences of adolescents with Down syndrome. Data were obtained from two groups. An experimental group was composed of nine male adolescents with Down syndrome (15–17 years old). Two participants were moderate in intelligence level while other seven were severely intellectually disabled. A comparison group consisted of nine male high school students (16–17 years old). Participants performed both unimanual and bimanual tapping tasks with one self-paced test trial after three audible-synchronized practice trials with concurrent feedback of force output. All tasks consisted of a target force of 2N and a target intertap interval of 500 ms. Adolescents with Down syndrome exhibited a greater magnitude of positive constant error and variable error for peak force than typical adolescents. They also exhibited a greater magnitude of negative constant error and variable error for intertap interval than typical adolescents. Although normally developing comparison adolescents exhibited a linear relationship between peak force and press duration or time-to-peak force, the relationship was not familiar to adolescents with Down's syndrome. This may suggest differences in the manner of motor unit recruitment between the group with Down's syndrome and comparison adolescents. On the other hand, there was no difference between unimanual and bimanual tasks for variable error of intertap interval in adolescents with Down's syndrome. Because people with Down syndrome have exhibited a thinner corpus callosum than typical people, they may be unable to combine the output of two separate timing systems.

Chapter 81 - The author have shown promising results of Assisted Cycling Therapy (ACT) for improving executive functioning in adolescents with Down syndrome (DS). The current study examines the one month retention of executive function benefits gained by adolescents with DS. Fifteen participants were randomly assigned to voluntary cycling (VC; i.e., self-selected cadence) or Assisted Cycling Therapy (ACT; i.e., 65% faster than self-selected cadence accomplished by a motor). Both cycling groups rode a stationary bicycle, for 30 minutes, three times a week, for eight weeks. At the beginning (i.e., pre-test) and end (post-test) of the 8-week session, and at a one month retention (follow-up), three executive functions including set-switching, inhibition, and cognitive planning, were measured. The results showed improved cognitive planning and set-switching for the ACT group after 8 weeks of intervention and these improvements were maintained for one month after the intervention. However, no significant differences were found between the cycling groups for our measure of inhibition. Thus, our results suggest that, especially in regards to cognitive planning and set switching, ACT may lead to relatively permanent changes in the brain.

Chapter 82 - Down syndrome (DS), well known as trisomy 21, occurs in one in one out of 700-1000 live births in all ethnic groups. DS is a very common cause of mental impairment and children with DS present with a variety of medical issues, including cardiovascular defects, endocrine problems, neurodevelopment disorders, hematological problems, gastrointestinal and sleep dysfunctions, visual and hearing impairment. It is well known that there is an association between DS and autoimmune disorders. Thyroid dysfunction (mostly autoimmune hypothyroidism) is the most typical endocrine disorder in individuals with this syndrome (affecting 0 to 66% of these patients). In these patients, in contrast with the general population, there are not substantial differences of incidence between sexes. It can be either congenital or acquired, and usually presents as a subclinical disorder. Hyperthyroidism as well is more commonly seen in people with DS than in the general population, and the phenotypic

metamorphosis from hypothyroidism to hyperthyroidism is more frequently seen. Moreover it is described in the literature an increased frequency of shortness of stature, diabetes mellitus, and nutritional disorders (overweight and obesity) in children with DS. An increased oxidative stress, probably due to the over expression of the gene for Cu/Zn superoxide dismutase (*SOD1*) located in chromosome 21, is observed in DS people and this fact may play a role in the higher prevalence and severity of a number of clinical conditions linked with the syndrome, as well as the accelerated ageing observed in these individuals. An endocrine follow up is required for these individuals, in order to early detect any subclinical abnormalities and prevent as many consequences as possible.

Chapter 83 - Autosomal dominant polycystic kidney disease (ADPKD) is an inherited genetic disorder that results in progressive renal cyst formation and ultimately loss of renal function. Mutation in either *PKD1* or *PKD2*, which are the genes coding for polycystin-1 and polycystin-2, respectively, is the main cause of the disease. The mutation in *PKD1* accounts for 85% of all ADPKD cases, whereas only 15% of ADPKD cases result from *PKD2* mutations. ADPKD is a systemic disorder associated with cardiovascular, portal, pancreatic and gastrointestinal systems. ADPKD is a ciliopathy, a disease associated with abnormal primary cilia. Non-motile primary cilia, functioning as mechanosensory organelles, have been an intense research topic in ADPKD. It has been shown that both structural and functional defects in primary cilia result in cystic kidney and vascular hypertension. In particular, polycystin-1 and polycystin-2 are co-localized to primary cilia and are responsible for mechanosensory induced calcium influx in response to fluid-shear stress. Based on the multiple signaling pathways in ADPKD, different molecular targets have been developed for potential therapies.

Chapter 84 - Hereditary Haemorrhagic Telangiectasia (HHT) or Rendu Osler Weber syndrome (OMIM 187300/ORPHA774) is a vascular hereditary autosomic dominant multiorgan dysplasia. Prevalence is in between 1 to 5,000/8,000 inhabitants around 65,000 in Europe, and 200,000 in USA); although due to founder effect, and insulation, it is higher in some regions as the Jura in France, Funen Island in Denmark and Caribbean Dutch Antilles where the prevalence may be 1 in 1,200 inhabitants. Diagnosis is based on the clinical criteria of Curaçao: epistaxis, telangiectases, first degree relative with HHT, and visceral arteriovenous malformations (AVMs), mainly in lung, liver and brain. For a positive diagnosis, 3 out of the 4 previous criteria are required. A positive genetic test implies also a positive diagnosis. The clinical diagnosis requires then a detailed medical screening, with involvement of different medical specialties. Penetrance of the disease is variable increasing with age. Pulmonary arteriovenous malformations (PAVMs) occur in approximately 50% of patients, hepatic involvement in up to 70%, brain AVMs in 10% and spinal in 1%. However the most frequent clinical manifestation of HHT is epistaxis (nose bleeding) normally from light to moderate that affects 93% of patients and is present before the age of 21 in 90% of cases. The genetic origin of the disease is due to mutations of genes involved in the TGF- β pathway, critical for the normal development of blood vessels. The first gene identified was *Endoglin* (*ENG*), responsible for the 39-59% of the HHT cases (HHT 1); shortly after, *ALK1*/*ACVRL1* was discovered to be involved in 25-57% of cases (HHT2). In around 2% of the HHT patients, the mutation is located in the *MADH4/Smad4* gene leading to a combined syndrome of Juvenile Polyposis and HHT (JPHT). A third and a fourth locus have been mapped on chromosomes 5 and 7 with no genes identified at the moment. Endoglin plays a key role in vasculogenesis and arterial/venous differentiation in embryos, as well as in angiogenesis and neovascularization processes in the adult; ALK1 is responsible for the events occurring during the activation phase

of angiogenesis. Haploinsufficiency is accepted as the mechanism of pathogenicity for the HHT.

Chapter 85 - Osteogenesis imperfecta is the most common heritable cause of fractures in children. It is not a single disorder but a large group of diseases most, but not all, being caused by defects of the genes coding for collagen. Autosomal dominant inheritance is the most common finding in familial cases but new mutations occur. Autosomal recessive inheritance does occur and mosaicism is recognized. The great molecular heterogeneity is reflected in great clinical and radiological variation. Some cases are so severe that survival beyond intra-uterine life is impossible. At the other extreme some patients, undoubtedly affected their family history, have few fractures and live normal lives. Fractures often occur spontaneously and previously asymptomatic fractures in various stages of healing are often found radiologically. While most symptomatic fractures are diaphyseal, all types of fractures including metaphyseal fractures, rib fractures and skull fractures do occur. Modern management involves good orthopaedic surgery; it is particularly important to avoid prolonged immobilisation of limbs to avoid superimposed osteopenia. Drug therapy, particularly with pamidronate, may be appropriate in children with the more severe forms of the disorder. Specific attention may be needed to scoliosis, basilar invagination or deafness. Good occupational therapy to maximise mobility is important. Children with osteogenesis imperfecta have normal intelligence and good education is vital.

Chapter 86 - The sudden rise of new biochemical and molecular techniques, have enabled a better understanding of the physiological and biochemical bases of the tumorigenesis, leaving clear that cancer is a "*genetic condition*". Breast cancer is one of the most common cancers in women, affecting one in six women among 40-59 years in the world; so it has been widely studied. Unlike the majority of genetic diseases, in which the presence of a mutation in a particular gene is sufficient for delineation of a phenotype (monogenic); in breast cancer, the simple presence of a mutation in a particular gene is not enough to explain it. Approximately 90% of breast cancer cases occur sporadically and the majority of cases are caused by mutations in the *BRCA1* or *BRCA2* gene. However, in 5-10% of cases of breast cancer has been identify an autosomal dominant transmission, as well as mutations in specific genes such as *TP53*, *PTEN*, *CHECK2* *STK11* among others, that considerably increase the susceptibility to this condition. Autosomal dominant transmission of this disease has opened a new chapter in cancer medicine since the presence of any of these mutations in a patient, forces the doctor to carry out a deep investigation of the condition in order to establish a prognosis, as well as effective strategies for survival and family prevention. This chapter makes a brief revision of the autosomal dominant disorders Li-Fraumani syndrome, Cowden Disease and Peutz-Jeghers syndrome, which have a high susceptibility to development of breast cancer.

Chapter 87 - Fragile X syndrome (FXS) is the most common cause of familial intellectual disability and the most commonly known single gene causing autism spectrum disorders. The incidence varies according to the populations; it is well-accepted that 1/4,000 males and 1/6,000 females are affected, and 1/250 females and 1/800 males are carriers. The main clinical manifestations are intellectual disability, dimorphic traits and behavior disturbances. The syndrome is inherited as a dominant X-linked trait with reduced penetrance (80% for males and 30% for women). This syndrome is due to a functional loss of the *FMR1* gene product, Fragile X Mental retardation Protein (FMRP), and, in most cases it is caused by a CGG repeat expansion in the *FMR1* promoter. The repeat is from 6 to 55 CGGs long in the normal population while in patients with FXS the repeat number is over 200 CGGs (full mutation

FM). This number of CGGs generally leads to methylation of the repeat and the promoter region, which is accompanied by silencing of the *FMR1* gene. The absence of the FMR1 protein, FMRP, is the cause of the intellectual disability in these patients. Individuals with 55 to 200 CGGs carry a premutation (PM). All affected children have carrier mothers (full mutation [FM] or PM) with a 50% of chance of having another affected child in future pregnancies. Female PM carriers are at risk of developing primary ovarian insufficiency (FXPOI). Elderly PM carriers (males and females) may develop a progressive neurodegenerative disorder called fragile X-associated tremor/ataxia syndrome (FXTAS). The *FMR1* gene is responsible for different disorders depending on the length of the CGG tract and the molecular mechanism. The Fragile X syndrome is due to a loss of function, and FXPOI and FXTAS are due to a toxic gain of function of the mRNA or repeat-associated-non-AUG translation. At present, there is no treatment, although several studies are ongoing in both human and animal models. The present and the following chapters review the current status of the wide spectrum of different pathologies related to the *FMR1* gene.

Chapter 88 - Fragile X-associated primary ovarian insufficiency (FXPOI) is among the family of disorders caused by the expansion of a CGG triplet repeat in the *FMR1* gene. FXPOI is a new clinical entity in which, carrier premutation (PM) females (with 56 to 200 CGG repeats) present early ovarian dysfunction, with menopause occurring 5 years earlier than non-carrier family members. It has been estimated that 2-6% of all women with premature ovarian failure and a normal karyotype have a PM. Therefore, *FMR1* testing is recommended in all women with confirmed ovarian failure; i.e., cessation of the menstrual cycle during three-four months with elevated FSH levels of >30U/L. Despite abundant literature, all authors agree that only a subset of PM carriers develop FXPOI (about 13-26%), with the precise molecular mechanisms of how the *FMR1* premutation causes FXPOI not being well understood. Nonetheless, recent studies have attempted to provide some insight into these mechanisms. This chapter summarizes some of these studies. Among these reports, the most important findings are: 1) the significant positive association of repeat size with POI, demonstrating that women with fewer than 100 repeats have an increased risk of FXPOI, and 2) the hypothesis that the *FMR1* PM may have a toxic RNA gain-of-function effect on ovarian follicle dynamics. These findings have also been demonstrated in rodent models in which the *FMR1* gene protein (FMRP) is highly expressed in oocytes which are important for folliculogenesis. Indeed, the two PM mouse models studied to date have shown evidence of ovarian dysfunction and increased expression of *FMR1* mRNA in the ovary.

Chapter 89 - Fragile X-associated tremor/ataxia syndrome (FXTAS) is a late-onset inherited neuropsychiatric degenerative disorder that occurs predominantly in male carriers of the *FMR1* premutation (55-200 CGG repeats). *FMR1* premutation is relatively frequent in the general population, affecting approximately 1 out of 800 males and 1 out of 250 females, and leading to symptoms of FXTAS in up to 1 in 3,000 men older than 50 years. Clinical symptoms in FXTAS patients usually begin with an action tremor. After that, different findings including ataxia (balance problems with frequent falling), and more variably, loss of sensation in the distal lower extremities and autonomic dysfunction (e.g., impotence, hypertension, and loss of bowel and bladder function), may occur, and gradually progress. Molecular mechanism leading to FXTAS is distinct from the *FMR1* silencing mechanism and/or a deficit in FMRP operating in fragile X syndrome. Individuals with *FMR1* premutation alleles have markedly elevated levels of expanded CGG-repeat *FMR1* mRNA, which is thought to have a toxic gain-of-function. Since 2001, when FXTAS was first described, the advancement of our understanding

of the clinical phenotype as well as the molecular pathophysiology has occurred very quickly. The aim of this chapter is to present the most recent advances in the current knowledge of FXTAS.

Chapter 90 - This chapter describes the psychopathological alterations of the different phenotypes associated with the *FMR1* gene. Fragile X patients present enormous functional impairment with a behavioral phenotype of hyperactivity and impaired attention, marked anxiety, with poor eye contact, affective lability, aggression, self-injurious behavior and autistic features. Since its first description the basic formulation of the fragile X behavioral phenotype has remained intact to the present day, with substantial confirmation of these basic findings in subsequent studies. Autism is one of the most recognized and severe behavioral abnormalities observed in males with fragile X syndrome (FXS) and this syndrome is the leading known monogenic cause of autism, accounting for approximately 5% of autism cases. Approximately 30–50% of FXS individuals meet full Diagnostic and Statistical Manual of Mental Disorders DSM-IV-TR criteria for autism with 60–74% fulfilling criteria for an autism spectrum disorder (ASD). Attention deficit and hyperactivity disorder (ADHD) is the most common diagnosable condition in FXS patients, with most males meeting formal criteria at some point in their lives. In children with FXS, ADHD is reported to be characterized by more inattentiveness, restlessness, fidgetiness and impulsivity. However, affective symptoms can be severe and disruptive, and are a common target for psychopharmacologic intervention. Several clinical subgroups present a higher risk for presenting anxiety outcomes, including children with FXS. Males with FXS display a broad range of anxiety symptoms, but these symptoms often do not fit into the established categories of major anxiety disorders employed by the DSM. Regarding individuals carrying a premutation there is a growing body of literature suggesting that neuropsychiatric features of fragile X-associated tremor/ataxia syndrome (FXTAS) follow a fronto-subcortical pattern with primary impairments in executive function and increased vulnerability to mood and anxiety disorders. Increased rates of psychiatric symptoms may represent early markers of neurodegenerative diseases and have also been reported among *FMR1* premutation carriers without FXTAS. On the other hand, several studies have reported an excess of intermediate *FMR1* alleles in patients with cognitive and/or behavioral phenotypes. Numerous studies have investigated neuropsychological phenotypes among premutation allele carriers in women, but no definitive profile has been achieved. An increased risk of anxiety and mood disorders among premutation allele carriers has not been established, although they seem to be more common in these subjects than in controls.

Chapter 91 - The expansion of the CGG trinucleotide located within the 5'UTR of the *FMR1* gene is involved in a growing number of diseases; the most well-established are Fragile X Syndrome (FXS), Fragile X Tremor/Ataxia Syndrome (FXTAS) and Fragile X Primary Ovarian Insufficiency (FXPOI). Whereas full mutation alleles (>200CGGs) are responsible for the FXS, smaller expansions called premutation alleles (55-200CGGs) are associated with FXTAS and FXPOI. Numerous evidence have currently been reported suggesting that premutation alleles give rise to an increased risk for carriers of these alleles in relation to additional medical, psychiatric and cognitive features which occur at a greater frequency than what would be expected for the general population. In this chapter, the author review the clinical features including peripheral neuropathy, immune-mediated disorders, migraines and neurocognitive involvement which have been suggested to be associated with premutation alleles. In addition, the current understanding of the pathogenic molecular mechanisms that give rise to the spectrum of *FMR1* premutation associated disorders is also reviewed. Although

further research is needed in order to shed light on the factors underlying the common incomplete penetrance applicable to all phenotypes associated with the premutation, it is likely that a combination of environmental and genetic factors with differences in intrinsic susceptibility may modulate the appearance and the severity of these disorders.

Chapter 92 - Fragile X syndrome is the most common form of inherited intellectual disability, with an estimated incidence of 1 in 4,000 males and 1 in 6,000 females. Each diagnosis of an *FMR1* mutation has far reaching clinical and reproductive implications for the extended family. Until now genetic counseling was offered based on the expansion risk in premutation carrier women, but the description of *FMR1*-associated disorders has increased the complexity of the genetic counseling for FXS families, especially *FMR1* premutation carriers. Male individuals carrying full mutated alleles present with intellectual disability while the penetrance is incomplete in females (30-50%). Premutation allele carriers are intellectually unaffected, but several *FMR1* premutation-related disorders have been described. The most prevalent are fragile X-associated primary ovarian insufficiency and fragile X-associated tremor/ataxia syndrome, but behavioral features such as impaired executive function, social deficits or anxiety have also been related to several *FMR1* premutation carriers. Premutation women have 50% of risk of transmitting a premutation/full mutation allele to their offspring, depending on the CGG expansion repeat and the presence of AGG interruptions. On the contrary, premutation men carriers will only transmit the premutation allele to their daughters. Some issues such as risk assessment for intermediate alleles and the clinical prognosis for females with full mutations still remain challenging. Genetic counselors must have an updated and solid understanding of this genetic condition and the *FMR1*-associated disorders in order to cover all the counseling aspects of these disorders.

Chapter 93 - Fragile X Spectrum includes three different clinical conditions Fragile X Syndrome (FXS), Fragile X-Associated Tremor and Ataxia (FXTAS), and Fragile X-Associated Premature Ovarian Insufficiency (FXPOI). Treatment of FXS is mainly symptomatic and it is addressed to improve or make disappear some of the more dyscapacitating symptoms like hyperactivity, deficit attention disorder and behavioral problems of language anomalies. Clinical trials are in course focusing on new discovered therapeutical targets (i.e., mGluR). Treatment of FXTAS and FXPOI are also mainly symptomatic and should be individually prescribed and modified depending on the clinical evolution.

Chapter 94 - Over the course of less than a decade, whole genome sequencing has progressed from being one of our nation's boldest scientific aspirations to becoming a readily available technique for determining the complete sequence of an individual's deoxyribonucleic acid (DNA)—that person's unique genetic blueprint. With this tremendous advance comes the accumulation of vast quantities of whole genome sequence data and complex questions of how—across a multitude of clinical, research, and social environments—to protect the privacy of those whose genomes have been sequenced. Collections of whole genome sequence data have already been key to important medical breakthroughs, and they hold enormous promise to advance clinical care and general health moving forward. To realize this promise of great public good ethically, individual interests in privacy must be respected and secured. Large-scale collections of genomic data raise serious concerns for the individuals participating. One of the greatest of these concerns centers around privacy: whether and how personal, sensitive, or intimate knowledge and use of that knowledge about an individual can be limited or restricted (by means that include guarantees of confidentiality, anonymity, or secure data

protection). Because whole genome sequence data provide important insights into the medical and related life prospects of individuals as well as their relatives—who most likely did not consent to the sequencing procedure—these privacy concerns extend beyond those of the individual participating in whole genome sequencing. These concerns are compounded by the fact that whole genome sequence data gathered now may well reveal important information, entirely unanticipated and unplanned for, only after years of scientific progress. Another privacy concern associated with whole genome sequencing is the potential for unauthorized access to and misuse of information. For example, in many states someone could legally pick up a discarded coffee cup and send a saliva sample to a commercial sequencing entity in an attempt to discover an individual's predisposition to neurodegenerative disease. The information might then be misused, for example, by a contentious spouse as evidence of unfitness to parent in a custody case. Or, the information might be publicized by a malicious stranger or acquaintance without the individual's knowledge or consent in a social networking space, which could adversely affect that individual's chance of finding a spouse, achieving standing in a community, or pursuing a desired career path. Realizing the promise of whole genome sequencing requires widespread public participation and individual willingness to share genomic data and relevant medical information. This, in turn, requires public trust that any whole genome sequence data shared by individuals with clinicians and researchers will be adequately protected. Current U.S. governance and oversight of genetic and genomic data, however, do not fully protect individuals from the risks associated with sharing their whole genome sequence data and information. In particular, a great degree of variation exists in what protections states afford to their citizens regarding the collection and use of genetic data. Only about half of the states, for example, offer protections against surreptitious commercial genetic testing. Currently, the majority of the benefits anticipated from whole genome sequencing research will accrue to society, while associated risks fall to the individuals sharing their data. This report focuses on reconciling the enormous public benefits anticipated from whole genome sequencing research with the potential risks to privacy of individuals, and the protections that must be foremost in our minds as the author focus our policies to facilitate such privacy and progress.

Chapter 95 - Congress has considered, at various points in time, numerous pieces of legislation that relate to genetic and genomic technology and testing. These include bills addressing genetic discrimination in health insurance and employment; personalized medicine; the patenting of genetic material; and the quality of clinical laboratory tests, including genetic tests. The focus on these issues signals the growing importance of the public policy issues surrounding the clinical and public health implications of new genetic technology. As genetic technologies proliferate and are increasingly used to guide clinical treatment, these public policy issues are likely to continue to garner considerable attention. Understanding the basic scientific concepts underlying genetics and genetic testing may help facilitate the development of more effective public policy in this area. Most diseases have a genetic component. Some diseases, such as Huntington's Disease, are caused by a specific gene. Other diseases, such as heart disease and cancer, are caused by a complex combination of genetic and environmental factors. For this reason, the public health burden of genetic disease is substantial, as is its clinical significance. Experts note that society has recently entered a transition period in which specific genetic knowledge is becoming critical to the delivery of effective health care for everyone. Therefore, the value of and role for genetic testing in clinical medicine is likely to increase significantly in the future.

Chapter 96 - Cancer is a major health problem worldwide and an early effective diagnosis would ensure timely management, impacting on the quality of life, the patients overall well being and longevity. There is no single test that can accurately diagnose cancer. An effective diagnostic test should be able to confirm or eliminate the presence of disease, monitor the disease process, and plan for and evaluate the effectiveness of treatment. Though there is a wide array of methods to diagnose cancer, an effective biomarker is still an unmet medical need. Conventional tests use single genes or discrete pathways. Cancer is a consequence of multiple changes occurring both in parallel and in sequence in the macromolecules of the cell. Earlier only gross end points were possible to be identified and measured, but today with technological advances it has become possible to interrogate events that are very early and at scales hitherto irresolvable. Thus changes in these cellular events are studied at different levels. DNA changes in cancer are expressed in terms of gross chromosomal anomalies or could be in the sequence of the gene or gene product/protein. As researchers learn more about the mechanisms of cancer, new diagnostic tools are constantly being developed and existing methods refined. Diagnostic procedures for cancer may include imaging, laboratory tests (including tests for tumor markers), tumor biopsy, endoscopic examination, surgery or genetic testing. This chapter draws attention to the critical events in pathobiology of cancer as is resolved by today's technological progress while compiling major biomarkers enabling improved diagnosis and reviewing some putative biomarkers for translation from bench to bedside.

Chapter 97 - The advent of massively parallel sequencing has changed the interrogation process of the human genome and now provides a high resolution and global view of the genome which is beyond research applications. Together with powerful bioinformatics tools, these next generation sequencing technologies have revolutionized fundamental research and have important consequences for clinically actionable tests, diagnosis and treatment of rare diseases and cancers. Today, molecular testing is commonly used to confirm clinical diagnosis of specific diseases; it requires that a clinician specify the gene or mutation to test and, in return, will receive information only about this sequence. Despite relative successes, a large number of patients receive no accurate diagnosis, even after many expensive molecular investigations. A clear paradigm shift has taken place in the health network with the introduction of the exome sequencing in molecular diagnostic lab. In this chapter, the impact of the implementation of high throughput sequencing technologies on molecular diagnosis and on the practice of medicine, with an emphasis in paediatrics, is reviewed. The author compared well-established genetic tests, using examples from our molecular diagnostic lab, to the recent exome sequencing applications. The genetic tests can fall into three main categories: 1) Mendelian Single Gene Disorder tests that include targeted mutation and targeted gene approaches 2) Genetic Disease Panels which are composed of a few to a dozen genes and 3) Exome or Genome approaches, which interrogate either the entire coding sequences of the 22,333 human genes or the entire human genome. For each of these categories, advantages and limitations are discussed. The author devoted a section on the future of molecular diagnosis and discuss which tests will subsist and which one may be soon abandoned. Massively parallel sequencing is transforming the molecular diagnostic field: it offers personalized genetic tests and generates new ethical challenges. Important questions like incidental findings and possible forms of discrimination are addressed. Finally, the author conclude with a section on the future directions surrounding the application of these multimodal molecular approaches in general and their putative applications in neonatal intensive care units.

Chapter 98 - Viral vectors engineered to carry transgenic sequences can be delivered into discrete tissues or anatomical structures to express specific transgenes into the transduced cells. Therefore, they are useful tools to produce specific, transient and localized knockout, knockdown, ectopic expression or overexpression of a gene, leading to the possibility of analyzing both *in vitro* and *in vivo* molecular basis of relevant functions. Replication-incompetent helper-dependent amplicon vectors, derived from herpes simplex virus type-1 (HSV-1) are devoid of viral genes. Thus, these vectors have great advantages as tools for *in vitro* and *in vivo* gene transfer and, in particular (i) minimal toxicity or induction of adaptive immune responses, and (ii) large transgene capacity, being able to carry up to 150 kbp of foreign DNA. In addition, these vectors have (iii) widespread cellular tropism: amplicons can experimentally infect several cell types, either quiescent or not, though naturally HSV-1 infects mainly neurons and epithelial cells, and (iv) absence of insertional mutagenesis, since the viral genome does not integrate into the host cell genome. These vectors have been used both on basic and applied research, and they have revealed as most suitable tools to study complex functions involving the nervous system, such as anxiety, sexual behavior, learning and memory. In addition, amplicon vectors are being used for the development of new experimental gene therapy approaches, both for inherited and acquired diseases affecting the nervous system, including neurodegenerative diseases. Although several technological improvements have been achieved in the last decade, some difficulties regarding these appealing vectors remain still unresolved, such as the inability to generate large amounts of high-titer fully helper-free vectors and the fact that expression from the transgenic sequence delivered by the vectors is generally unstable, often leading to a complete silencing of expression after a few weeks. To overcome these obstacles and to improve these vectors, the author have recently modified (a) the amplicon genome, in order to fully delete bacterial sequences and (b) developed novel complementing cell lines, in order to improve helper-free vector production and to render amplicon stocks compatible with clinical trials. In this review article the author briefly review data supporting the potential of HSV-1-based amplicon vector model for gene delivery in primary cultures of neural cells and into the brain of living animals.

Chapter 99 - Papillomaviruses (PVs) infect the epithelium of amniotes, where they can cause tumours or persist asymptotically. PVs are classified in the *Papillomaviridae* family, that contains 29 genera of PVs isolated from humans (120 types), non-human mammals, birds and reptiles (69 types). PVs have circular double-stranded DNA genomes approximately 8 kb in size and typically contain eight genes. Studies aiming the identification of PVs genomes use techniques such as PCR with consensus primers, rolling circle amplification and metagenomic methods. Advances in papillomaviral genome research have allowed the knowledge of PVs diversity and evolution of the poorly known PVs genera types, revealing that there is still a limited understanding of PVs diversity. Particularly, recent studies in Bovine Papillomavirus (BPV) have shown the identification of novel BPV types and several putative new virus types in cattle. This chapter will show new contributions in PVs genome studies.

Chapter 100 - Viral particles are important tools in Molecular Biology, acting as carriers of genetic material, immunogenic antigens, adjuvants, or even directly combating antibiotic-resistant microorganisms and their biofilms in hospital and industrial environments. However, the efficient use of these particles requires extensive knowledge about their characteristics and components, including those involved in their regulatory mechanisms of genome transcription and protein synthesis. The exploration of this knowledge becomes a challenge especially for scientists analyzing the virions in their natural environment, due to their interactions with the

complex and diverse types of biological systems, which directly influence the regulation of the infective cycles. Thus, knowledge about viral genes, their function, organization, and modulation, beyond the comprehension of the viral components as parts of complex systems, consist of the main hurdles for the controlled and predictable handling and use of these particles. For this, the technology of Synthetic Synthesis of viral genomes is distinguished from traditional genetic engineering through the use of modularity and standardization to construct proof-of-principle systems and allow generalized circuits designs to be applied to different scenarios. This new technology is made possible thanks to advances in many areas of science, from the use of restriction enzymes until the development of techniques of genomic synthesis and sequencing, like the 454 Roche, Illumina, and SOLiD systems. This technology is becoming increasingly a multidisciplinary tool used in the investigations about these complex systems, as well in the engineering of new particles for the optimization of diverse viral functions and alterations in their infectivity and affinity, or even in the development of completely new organisms and features without the need for a template. Nevertheless, advances in this technology are still limited by the lack of dynamic techniques for monitoring biological systems and efficient and standardized circuits. Here, the author summarize the major characteristics of viral genomes, their organization and gene modulation, and highlight the main aspects of Synthetic Biology applied to viral genomes, as its main techniques and applications.

Chapter 101 - With increase of microbial and viral genome sequence data obtained from high-throughput DNA sequencers, novel tools are needed for comprehensive analyses of the big sequences data. An unsupervised neural network algorithm, Self-Organizing Map (SOM), is an effective tool for clustering and visualizing high-dimensional complex data on a single map. The author previously modified the conventional SOM for genome informatics on the basis of batch-learning SOM (BLSOM), by making the learning process and resulting map independent of the order of data input. Influenza virus is one of zoonotic viruses and shows clear host tropism. Important issues for bioinformatics studies of influenza viruses are prediction of genomic sequence changes in the near future and surveillance of potentially hazardous strains. To characterize sequence changes of influenza virus genomes after invasion into humans from other animal hosts and to study molecular evolutionary processes of their host adaptation, the author have constructed BLSOMs for oligonucleotide, codon, amino-acid, and peptide compositions in all genome sequences of influenza A and B viruses and found clear host-dependent clustering (self-organization) of the sequences. Viruses isolated from humans and birds differ in mononucleotide composition from each other. In addition, host-dependent oligonucleotide and peptide compositions that cannot be explained with the host-dependent mononucleotide composition are revealed by these BLSOMs. Retrospective time-dependent directional changes of oligonucleotide compositions, which are visualized for human strains on BLSOMs, can provide predictive information about sequence changes of the newly invaded viruses from other animal sources. Basing on this host-dependent oligonucleotide composition, the author have proposed a strategy for prediction of directional changes of virus sequences and for surveillance of potentially hazardous strains when introduced into human populations from nonhuman sources. Millions of genomic sequences from infectious microbes and viruses will become available in the near future because of their medical importance, and BLSOM can characterize such big data easily and support efficient knowledge discovery.

Chapter 102 - An oncogene is a modified gene, or a series of nucleotides that encode a protein, and direct the cell to the development of a neoplastic phenotype. Usually, oncogenes are involved in tumor development and increase the possibility that the development

(proliferation and differentiation) of a cell directs towards cancer. New researches indicate that small ribonucleic acids (RNA) of 21-25 nucleotides, called micro RNA (miRNA), can control these genes through down-regulation. The first oncogene was discovered in 1970 and named Src. Src was first discovered in a retrovirus of chickens. In 1976, J. Michael Bishop and Harold E. Varmus of the University of California showed that this oncogene was a defective proto-oncogene present in many organisms including humans. For their studies Bishop and Varmus were awarded of the Nobel Prize in 1989. A proto-oncogene is a normal gene that can become oncogenic due to mutations or to increased expression. Proto-oncogenes encode proteins that regulate the cell cycle and differentiation. They may also be involved in the signal transduction of the start of mitosis. A proto-oncogene becomes an oncogene even with minimum modifications of its original functions. There are two basic types of activation: 1) a mutation of nucleotides which produce a different protein causing: a) increased enzymatic activity of the protein; b) the loss of regulatory sites; and c) the creation of hybrid proteins; and 2) an increase of the concentration of proteins caused by: a) an increase of gene expression (through misregulation); b) an increase of stability (half-life) of the protein; and c) a duplication or amplification of the gene coding for the protein. Growth factors (GF), or fitogens, are usually secreted in a few cells specialized to induce proliferation in a paracrine, autocrine, or endocrine manner. If a cell that normally does not produce GF suddenly begins to produce them (because it has developed an oncogene), this induces the proliferation, without control, to adjacent cells (paracrine action) and to its cell type (autocrine action) increasing secretion. There are six known classes of protein kinases (PK) and related proteins that are potential oncogenes: 1) tyrosine kinase receptor (TKR), which becomes constitutively (permanently) activated, such as the epidermal growth factor receptor (EGFR), the platelet-derived growth factor receptor (PDGFR), and the vascular endothelial growth factor receptor (VEGFR); 2) cytoplasmic TK, such as TK enzymes of the Src family, Syk-ZAP-70 and Bruton's TK (BTK); 3) regulatory guanosine triphosphate (GTP)ase, like Ras; mutations that activate permanently Ras are found in 20-25% of all human tumors and up to 90% in some types of cancer, such as pancreatic ones; 4) cytoplasmic serine/threonine kinase and its regulatory units, such as Raf kinase and cyclin-dependent kinase (CDK); 5) adapter proteins in signal transduction (for example in the apoptotic pathway); and 6) transcription factors, for example the Myc gene. A large number of genes have been identified as proto-oncogenes. Most of them are responsible for the production of a positive signal that induces cell division. Other proto-oncogenes play an important role in the regulation of cell death. As mentioned before, the "altered" versions of these genes (oncogenes) may induce the cell to replicate unruly. Such a development can take place even in the absence of normal pro-growth signals, as for example the one provided by GF. A key feature in the activity of oncogenes is that a single altered copy is sufficient to induce an unregulated growth. Such behavior is in contrast with the one typical of tumor-suppressor genes (TSG) for which it is necessary that both copies of the gene are defective for triggering a process of abnormal cell division. Proto-oncogenes that have been identified until now have very different functions within the cell. Despite the differences in their normal functions, these genes all have the characteristic to contribute to unregulated cell division when present as mutated (oncogenic). The mutated proteins sometimes retain some features of their own, but are no longer sensitive to the regulation systems that determine and control the normal form of the protein itself. In this chapter the author overview the role of oncogenes in gynecological pathology.

Chapter 103 - Cancer is an uncontrolled cell growth caused by accumulation of genetic and epigenetic mutations in genes that normally play a role in the regulation of cell proliferation, survival, apoptosis and cell cycle. *Mutations are occurring mainly* in oncogenes, tumor-suppressor genes, microRNA genes, or as DNA repair defects and aberrant DNA methylation. Oncogenes encode proteins that control cell proliferation and/or apoptosis. Products of oncogenes can be classified into 6 groups by its biological activity: transcription factors, growth factors, growth factor receptors, signal transducers, chromatin remodeling and apoptotic regulators. The main changes related to oncogene activation are chromosomal translocations and mutations that can occur as early events or during tumor progression; whereas amplification usually occurs during the tumor progression. These alterations are usually somatic events, although germ-line mutations can also predispose to familial cancer. A single genetic change is rarely insufficient for developing a malignant tumor. Most evidences point to a multistep process of sequential alterations in a wide number of oncogenes, tumor-suppressor genes, or microRNA genes related with cancer. Recently, other mechanisms as the inflammation or alterations in the cellular metabolism have been associated with cancer. This chapter describes some of the key molecular mechanisms involved in the development and progression of cancer.

Chapter 104 - Recent understanding of oncogene regulation has uncovered an emerging new field of molecular cancer biology in which tumor suppressors and mediators are controlled through RNA regulation. Among the most critical players are microRNA (miRNA), also referred to as ‘oncomirs’, and Dicer, the major enzyme responsible for cleaving double-stranded RNA and forming the RNA induced silencing complex. These components are aberrantly expressed in cancer and among some tumor types are hypothesized to be causative to the etiology of malignancy. For example, prostate and colorectal cancers express abundantly high levels of Dicer mRNA while lung, ovarian and endometrial cancers express low levels of Dicer, which is believed to correlate to poor cancer prognosis. In addition, mutations of the Dicer encoding gene (*DICER1*) occur in non-epithelial ovarian cancers and pediatric tumor pleuropulmonary blastoma. Paradoxically, Dicer is a haploinsufficient tumor suppressor; the loss of a single allele of *DICER* enhances tumor growth where the loss of the second allele results in halting tumor proliferation. MicroRNA regulates oncogenic signaling pathways as well as the expression of tumor suppressors and oncogenes, making it a major contributor to the overall status of the cell and its malignant potential. The let-7 miRNA family members are well-known as tumor suppressor genes, which target and silence the Ras oncogene. On the other hand, miRNAs may induce tumor growth; one example is miR-17-19 cluster negatively regulating two tumor suppressor genes, PTEN and Bim. In this chapter, the regulation of oncomirs will be discussed with focus on the post-transcriptional control by miRNA biogenesis machinery, which consist Dicer as a major player.

Chapter 105 - Glioblastoma multiforme (GB) is the most common primary brain tumor among adults. Rapid tumor progression and diffuse invasion of brain tissue results in a poor prognosis despite advances in the understanding of the tumor’s molecular biology. Recently, targeted therapy has been introduced as a potential therapeutic option in several types of cancer. Dysregulation of the epidermal growth factor receptor (EGFR) has been identified in a number of different malignant tumor entities, such as GB. Despite promising reports from preclinical studies, clinical trials yielded no significant improvement of outcomes of patients with GB who were treated with anti-EGFR-targeted agents. Molecular mechanisms underlying resistance to this treatment approach have become a focus of scientific efforts in the last years. The variations and complexity of EGFR signaling pathways demand a composite therapeutic strategy to

quench alternative signaling routes which otherwise might enable cancer cell survival and subsequently tumor progression.

Chapter 106 - Glioblastoma multiforme (GB) is the most common primary brain tumor among adults. Rapid tumor progression and diffuse invasion of brain tissue results in a poor prognosis despite advances in the understanding of the tumor's molecular biology. Recently, targeted therapy has been introduced as a potential therapeutic option in several types of cancer. Dysregulation of the epidermal growth factor receptor (EGFR) has been identified in a number of different malignant tumor entities, such as GB. Despite promising reports from preclinical studies, clinical trials yielded no significant improvement of outcomes of patients with GB who were treated with anti-EGFR-targeted agents. Molecular mechanisms underlying resistance to this treatment approach have become a focus of scientific efforts in the last years. The variations and complexity of EGFR signaling pathways demand a composite therapeutic strategy to quench alternative signaling routes which otherwise might enable cancer cell survival and subsequently tumor progression.

Chapter 107 - Glioblastoma multiforme (GB) is the most common primary brain tumor among adults. Rapid tumor progression and diffuse invasion of brain tissue results in a poor prognosis despite advances in the understanding of the tumor's molecular biology. Recently, targeted therapy has been introduced as a potential therapeutic option in several types of cancer. Dysregulation of the epidermal growth factor receptor (EGFR) has been identified in a number of different malignant tumor entities, such as GB. Despite promising reports from preclinical studies, clinical trials yielded no significant improvement of outcomes of patients with GB who were treated with anti-EGFR-targeted agents. Molecular mechanisms underlying resistance to this treatment approach have become a focus of scientific efforts in the last years. The variations and complexity of EGFR signaling pathways demand a composite therapeutic strategy to quench alternative signaling routes which otherwise might enable cancer cell survival and subsequently tumor progression.

Chapter 108 - This chapter describes the radiographic appearance and distribution of plexiform neurofibromas (PNs) in NF1. Although PNs are histologically benign tumors, they are the source of significant morbidity including disfigurement, pain, functional impairment and they can undergo malignant transformation. Identifying targeted agents that slow the growth or decrease the size of PNs is an area of intense research. Volumetric MRI analysis of PNs is helpful in detecting treatment response and progression in these large and complex shaped tumors with greater sensitivity compared to 1-dimensional or 2-dimensional measurements.

Chapter 109 - Neurofibromatosis Type 1 (NF1) is an autosomal dominant systemic disease. Up to fifty percent of patients with NF1 are reported to have concomitant vascular abnormalities, incidence which increases the mortality especially in young patients. Among the complications of giant neurofibromas, spontaneous rupture and massive hemorrhage has been reported, leading to limb loss and death as well. The resection of larger neurofibromas is a challenging procedure because the risk of uncontrolled hemorrhage is much higher. In this chapter, the author present a review of the medical literature of the methods that have been used to control intraoperative bleeding in large neurofibromas. The author also discuss a novel surgical technique, which includes the ligation of the base of the giant neurofibroma tissue using a continuous loop-shaped suture. This method makes the operation field relatively bloodless and facilitates identification and ligation of the intralesional vessels. In addition, this surgical technique is less complicated and easier to perform and compared to others.

Chapter 110 - Patients with Neurofibromatosis 1 (NF 1) suffer from a myriad of medical problems including benign as well as malignant tumors. Malignancy is the most common cause of death in affected individuals, and reduces life expectancy by 10-15 years. Amongst other tumors, patients with NF1 carry an elevated risk of specific central nervous system (CNS) tumors. The most common NF1-associated CNS tumors are low-grade gliomas (LGG) such as optic pathway gliomas, hypothalamic gliomas, and other parenchymal gliomas located in the brainstem, cerebellar peduncles, globus pallidus, and midbrain. In addition to CNS tumors, patients with NF1 also develop peripheral nervous system (PNS) tumors such as neurofibromas and schwannomas. These tumors arise most commonly from major peripheral nerves such as the radial and ulnar nerve. These are benign tumors however can cause significant disfigurement, pain and depending on the location specific neurological complications. Malignant transformation of these tumors leads to malignant peripheral nerve sheath tumors (MPNST). These tumors occur in less than 5% of children with NF1, but are the leading cause of mortality in adult patients with NF1. Significant advances in our understanding of LGG have been achieved over the last several years. Several genetic aberrations, which activate the MAPK pathway have been identified in the majority of LGGs, most notably the BRAF-KIA1549 fusion protein and the activating BRAFV600E mutation. Specific inhibitors of MEK1/2, the immediate downstream target of BRAF, are currently being tested in the clinic for children with LGGs. Treatment for symptomatic plexiform neurofibromas remains a clinical challenge for most pediatric neuro-oncologists. Recent studies have shown promise to use pegylated (PEG)-interferon-alpha-2b. Other treatment strategies also target the MAPK pathway for these tumors. Treatment of MPNST remains under investigation and outcome remains poor. Most patients are currently treated with a combination of surgery, radiation and chemotherapy. In this chapter, the author will outline NF1 associated CNS and PNS tumors and discuss current treatment approaches.

Chapter 111 - Optic pathway gliomas (OPG) occur in 15% of children with Neurofibromatosis type 1 (NF1) and will lead to visual deficits in up to half. Because this tumor rarely threatens life but often leads to uncorrectable and permanent vision loss, preserving vision is the primary objective in management of OPGs. However, measuring visual function with ophthalmology exams can be challenging in young children with NF1-associated OPG. Recently, a variety of surrogate outcome measures have been investigated to determine if reliable quantifiable markers of vision can be found. In this chapter, the author review the presentation and management of OPGs in children with NF1. The author discuss endpoints commonly used in clinical trials, including assessments of visual function and radiologic progression. Finally, the author investigate and compare recent putative surrogates of vision in OPG, and the author discuss their utility in identifying and following vision loss in children with NF1. Currently, visual acuity is the most reliable, comparable and quantifiable outcome measure available in the assessment of patients with OPG. However, novel physiologic and radiologic markers of vision loss may offer an important adjunct to the assessment of the child with NF1-associated OPG in the future.

Chapter 112 - Optic pathway gliomas (OPG) occur in 15% of children with Neurofibromatosis type 1 (NF1) and will lead to visual deficits in up to half. Because this tumor rarely threatens life but often leads to uncorrectable and permanent vision loss, preserving vision is the primary objective in management of OPGs. However, measuring visual function with ophthalmology exams can be challenging in young children with NF1-associated OPG. Recently, a variety of surrogate outcome measures have been investigated to determine if

reliable quantifiable markers of vision can be found. In this chapter, the author review the presentation and management of OPGs in children with NF1. The author discuss endpoints commonly used in clinical trials, including assessments of visual function and radiologic progression. Finally, the author investigate and compare recent putative surrogates of vision in OPG, and the author discuss their utility in identifying and following vision loss in children with NF1. Currently, visual acuity is the most reliable, comparable and quantifiable outcome measure available in the assessment of patients with OPG. However, novel physiologic and radiologic markers of vision loss may offer an important adjunct to the assessment of the child with NF1-associated OPG in the future.

Chapter 113 - This chapter provides an overview of the neurocognitive, behavioral and developmental aspects of the neurofibromatosis type 1 (NF1) phenotype. Investigations into the pathogenesis of cognitive dysfunction are also presented, with a focus on human neuroimaging studies and mouse models. These studies have provided major insights into the molecular and biochemical abnormalities associated with NF1 that impact on cognitive performance. Preclinical studies suggest that pharmacological correction of these abnormalities has the potential to normalize aspects of the NF1 cognitive phenotype. These are reviewed along with the rationale for ongoing and future human clinical trials.

Chapter 114 - The purpose of this chapter is to provide an overview of communication disorders observed among children and adults with Neurofibromatosis type 1 (NF1). In each section, terminology, prevalence and information regarding assessment for individuals in the general population will be presented. The literature describing communication disorders observed in the population of individuals with NF1 will be reviewed. Following a review of the literature, options for speech-language assessments for individuals with NF1 will be discussed.

Chapter 115 - Neurofibromatosis Type 1 (NF1) is a multisystem disorder, and cognitive impairment is its most common complication in childhood. Although patients with NF1 are at risk for significant clinical illnesses, most patients are only mildly affected and live healthy and productive lives. Most research in NF1 to date has been focused on defining the physical and cognitive deficits based on standardized testing, with little emphasis on their functional correlates. Evidently, student engagement in the classroom reflects, in a large part, self regulation skills which are influenced by temperament and higher order cognitive executive function processes. In particular, sustained attention, which comprises both task-oriented attention and low impulsivity, predicts academic and behavioral adjustment. The purpose of the present chapter is to identify predictors associated with school participation in a sample of children with NF1. A unique feature of this work is the examination of children's participation across different classroom activity components such as handwriting and cognitive skills, such as attention and executive function. Each of these classroom activities may require a unique set of functional skills to meet specific demands. Findings and insights presented in this chapter may help clarify the important factors supporting effective engagement by children with NF1 in school programs. The chapter describes the functional problems of children with NF1 in the classroom according to the International Classification of Functioning, Disability and Health–Children and Youth version (ICF-CY). The chapter includes current literature on NF1, using the framework provided by the ICF-CY in highlighting the holistic evaluation and interpretation of disabilities. In the first part it presents the ICF-CY conceptual model, defines the term 'ecological validity ' and details regarding two ecologically valid assessment tools (Virtual Classroom and functional questionnaire). The chapter subsequently describes the functional academic profile of children with NF1 from three points of view: attention profile,

academic skills in relation to executive profile and handwriting performance. The set of tasks composing each activity provides a useful indication of the factors that may underlie functional participation of children with NF1 in the classroom context. The chapter illustrates the functional profile with a case study and the author conclude the chapter with suggestions for further research.

Chapter 1

SPECIATION IN DIATOMS: PATTERNS, MECHANISMS, AND ENVIRONMENTAL CHANGE

Joshua T. Cooper^{1,*} and John P. Masly^{2,†}

¹Department of Microbiology and Plant Biology,

²Department of Biology, University of Oklahoma, Norman, OK, US

ABSTRACT

Diatoms represent one of the most speciose groups of organisms within the microeukaryota— they occupy almost every aquatic niche worldwide, provide important functions within ecosystems as a major contributor of carbon dioxide fixation from the atmosphere, and also serve as a major contributor to the base of the aquatic food web. Despite this striking example of biodiversity and their ecological importance, we know relatively little about the speciation processes at work in this group of organisms. In this chapter, we review the patterns of speciation in marine and freshwater diatoms with respect to their paleontological, environmental, and genetic evolutionary histories. We summarize the evidence for sex and hybridization among diatom species, and discuss recent work on understanding the mechanisms of reproductive isolation that limit gene flow in the microeukaryota. We also discuss aspects of diatom genome evolution that provide clues to the genetic basis of speciation in this group. Finally, we end with a discussion of a natural model system that presents a unique opportunity to address some of the outstanding questions in diatom speciation.

INTRODUCTION

Speciation and adaptation are two of the most important evolutionary processes that generate biodiversity. Although each of these areas of research has enjoyed a rich history of discovery, the vast majority of what we know about the mechanisms that govern these

evolutionary forces is limited largely to multicellular eukaryotic taxa. We know comparatively little about the speciation processes in the microeukaryotes, despite microeukaryota being one of the most speciose groups of organisms on the planet and their ecologically important role within the global carbon cycle. Among the microeukaryotes, diatoms represent the most speciose group, and are particularly important for global ecology and maintenance of the oceanic biogeochemical cycling. The diatoms fix an estimated 40–45% of oceanic production and fix approximately 20 Pg of carbon yearly (Mann 1999), which makes them more productive than all the Earth's rain forests combined. In relative terms, every fifth breath you take contains oxygen atoms derived from diatoms (Nelson et al. 1995; Field et al. 1998; Armbrust 2009).

The diatoms also form the foundation of almost every aquatic food web spanning marine to freshwaters. They are found wherever light and water are present, including saline lakes, freshwater springs, cave entrances, waterfalls, hot springs, and they also inhabit micro-aquatic environments including damp soils and even desert soils (which experience periodic moisture). Since their first appearance in the fossil record during the Upper Cretaceous, approximately 500 distinct genera of diatoms have evolved and been formally described; of these, at least 365 are extant with living representatives, and 132 are presumed extinct with representatives found only in the fossil record (Gersonde and Harwood 1990; Round et al. 1990; Tapia and Harwood 2002; Guiry and Guiry 2012; Silva 2012). However, some species thought to be extinct have been re-discovered recently: occasionally "living fossils" are found living in places like New Zealand tarn lakes (Vyverman et al. 1998), Lake Baikal (Edlund et al. 2000; Williams and Reid 2006), found under the ice or attached to seaweeds in Antarctica (Sutherland 2008), or in geographically isolated ancient desert valleys of Northern Mexico (Winsborough et al. 2009). Current estimates of species richness of diatoms vary greatly, but likely reside within the range of 10^4 to as many as 10^8 species (Round et al. 1990; Mann and Droop 1996).

Diatoms are a diploid group within the Stramenopiles (synonyms include Chromalveolates, Chromista, Heterokonts) and are characterized morphologically by highly ornamented and sculpted bipartite silicon dioxide (silica) shells called the frustule (two valves plus the girdle bands comprise the frustule; Figure 1). The biogenic silica ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$) that comprises the majority of the frustule material is similar in chemical properties to the gemstone opal, and is sequestered from the aquatic environment by specialized silica depositing vesicles (Li et al. 1989; Vrieling et al. 1999; Martin-Jézéquel et al. 2000). The frustule is constructed much like that of a hat box, with one large "box lid", the epitheca valve, that sits on top of and overlaps a smaller "box", the hypotheca valve (Figure 1). Located between the epitheca and hypotheca are several separate, concentric bands of silica called the girdle or cingulum. Both the epitheca and hypotheca possess a cingulum; the cingula act together to allow the cell to expand in height with the addition of each girdle band.

Although the vast diversity of diatoms has drawn the interest of evolutionary biologists since the mid-1800's, little work has been performed investigating the speciation processes and mechanisms at work in this group until relatively recently. Here, we review the progress made on understanding the process of speciation in diatoms and the evolution of reproductive isolation (RI) in relation to adaptation to the environment, and discuss prospects for future research directions in the microeukaryota.

Figure 1. Major morphological features of the diatom frustule. The top of the epitheca (the epivalve plus the epicingulum) is called the valve face. The epicingulum and hypocingulum are composed of several copulae (girdle bands) that allow the cell to expand or contract vertically. The nucleus (n) is often located in the center of a diatom cell, however, it can be moved to different parts of the cytoplasm via microtubules. The cytoplasmic region is bounded by the plasmalemma and silicalemma (dashed line), which secretes the cell wall. Within the cytoplasmic space there can be numerous discoid or singular plate-like chloroplasts (not shown).

PHYLOGENETIC RELATIONSHIPS

The silica frustules that are characteristic of all diatoms are dotted with highly organized pores that extend completely through the frustule. The pores enable diatoms to interact with the external environment via diffusion or active uptake of dissolved inorganic and organic substances from the surrounding water. The frustule is often covered on the exterior with polysaccharides or sulfated proteoglycans, whereas the inside of the frustule is coated in a separate organic layer called the diatopetum that protects the silica cell wall from dissolution and binds the siliceous cell wall components together (Hoagland et al. 1993; McConville et al. 1999). Frustule architecture and morphometry have been used to classify diatoms into genera based on overall shape and degrees of symmetry (Round et al. 1990), however, they differ in species-specific patterns and their functions in various biological processes (Kröger and Poulsen 2008). Studies of diatom valve morphogenesis—the processes of frustule silicification—have identified several phylogenetically informative characters within and between groups of diatoms capable of establishing either relatedness (Cox 2010, 2011) or seemingly homoplastic characters between unrelated genera (Cox and Williams 2000; Cox 2006). Further work is needed to understand both the genetic basis of these and other siliceous morphological characters to understand ancestor-descendant relationships with assessment of apomorphic and plesiomorphic characters on a phylogeny (Theriot et al. 2006).

Figure 2. Two possible placements of the diatoms within the Tree of Life. A) Phylogenetic placement adapted and generalized from Parfrey et al. (2010). SAR indicates the clade composed of Stramenopiles, Alveolates, and Rhizaria. B) Phylogenetic placement adapted and generalized from Keeling et al. (2005).

The precise position of diatoms within the higher Eukaryotic Tree of Life is debated. Diatoms are single celled photoautotrophic eukaryotic algae and form a phylogenetic clade separate from plants and opisthokonts (animals and fungi). Some studies place diatoms between the Stramenopiles, Alveolates and Rhizaria group (Parfrey et al. 2010; Katz et al. 2012), whereas other studies place them within the Chromalveolates (Keeling et al. 2005) (Figure 2). Regardless of the exact position of where diatoms reside within the Tree of Life, it is clear that they evolved via secondary endosymbiotic events evidenced within their genomes (Bowler et

al. 2008; Tirichine and Bowler 2011) and by the presence of double membrane structures observed within all diatom cells. Of the two complete diatom genomes that have been sequenced and assembled (*Thalassiosira pseudonana* and *Phaeodactylum tricornutum*) the gene identities appear to be a combination of red algae, green algae, bacterial genes, and genes common to animals (heterotrophic organisms) (Armbrust et al. 2004; Bowler et al. 2008). In addition to their diverse gene ancestry, their genomes are also highly divergent at the sequence level. Results of comparative genomic analyses between *T. pseudonana* and *P. tricornutum* show that these two species fall within the range of the divergence observed between humans (*Homo sapiens*) compared to pufferfish (*Takifugu rubripes*) and humans compared to tunicate (*Ciona intestinalis*).

Figure 3. Diatom size diminution series in three representative diatom genera from field samples that shows the generalized pattern of cell size reduction with successive mitotic divisions proceeding from left to right. A) Raphid diatom in the genus *Gomphoneis*. The raphe is the vertical slit structure seen in the middle of the valve through which the diatom extrudes microfilaments that allows for cell motility. B) Centric diatom in the genus *Stephanodiscus*. C) Araphid diatom in the genus *Diatoma*. Scale bars are 10 µm.

T. pseudonana and *P. tricornutum* each represent two classically defined groups based on overall morphological symmetry: centric diatoms (e.g., *T. pseudonana*) that possess radial symmetry and pennate diatoms (e.g., *P. tricornutum*) that possess bilateral symmetry around a

sternum and an elongate shape (Figure 3). Within the pennate diatoms, those with a raphe (raphid) and those without (araphid) are also subdivided. The raphe is a slit-like structure through the frustule that allows diatoms to exude microfilaments and move across substrates. Many diatomists recognize the classification of Round et al. (1990) who published the first truly comprehensive work on diatom biology using a combination of light microscopy, scanning electron microscopy (SEM), and documentation of both fossil and extant taxa. Their classification further divides “centric” and “pennate” diatoms into Coscinodiscophyceae (formerly the centric group), Bacillariophyceae, and Fragilariaceae (both formerly within the pennate group). The introduction of molecular sequence analyses into constructing the diatom phylogeny (Medlin et al. 1988) has produced additional groupings and subdivisions into the centric diatoms (Coscinodiscophyceae), multipolar or bipolar diatoms (Mediophyceae), diatoms with bilateral/pennate symmetry (Bacillariophyceae) along with several other variations (Medlin and Kaczmarska 2004). Theriot (2010), however, suggests that diatoms form grades along characteristic morphologies: the radial centric grade, the polar centric grade, araphid pennate grade, and the raphid pennate grade. Regardless of the subtle differences among these proposed groupings, the overall picture that seems to be emerging from these studies is that it appears centric diatoms— both radial and polar— appear to be ancestral. Araphid diatoms share a most recent common ancestor with raphid diatoms, which together shared a common ancestor with the polar centric diatoms (Figure 2).

REPRODUCTION IN DIATOMS

To understand the mechanisms of speciation at work in diatoms, it is important to understand how diatoms reproduce. The life cycle of diatoms is unique due to the constraints of the siliceous cell wall (Figure 4). During vegetative growth, cells reproduce via mitosis, and as a consequence of the siliceous frustule, they produce slightly smaller cells within the parent cell (Figure 3, Figure 4). Diatom size diminution was first described independently by Macdonald (1869) and Pfitzer (1869, 1871). Both authors observed that many diatom species experience a binomial progression of reduction during consecutive cell divisions. This so-called Macdonald-Pfitzer rule was later formalized by Lewis (1984) as a regular decrease in the average size of a daughter cell, but with an increase in the standard deviation within the cell lineage over the course of successive mitotic divisions. The diminution process continues until the cells reach a certain species-specific size threshold, at which time they enter sexual reproduction. These size thresholds generally occur between 30% of the original cell size in radially symmetric centric diatoms and 40% of the original cell size in bilaterally symmetrical species (Drebes 1977; Lewis 1984; Potapova and Snoeijjs 1997). (Although this phenomenon is common to many diatoms species, exceptions do occur in which diatoms utilize their girdle bands to prevent mitotic cell size reduction, or in some cases, experience sudden breaks in size reduction (Geitler 1935)).

During the sexual reproductive phase, centric/polar diatoms (and some araphid and raphid diatoms) undergo a process of oogamous reproduction in which two “sexes” produce haploid gametes— either 1-2 eggs or 4-128 motile, flagellated sperm (Drebes 1977). Sperm swim toward the non-motile egg cells and upon fusion create a diploid zygote called the auxospore that separates from the parental frustules (Figure 4). The auxospore cell then swells into an

enlarged sphere that exceeds the size of the parent cell from which it was derived. Within the auxospore, the zygote deposits two new epitheca valves via a silica deposition vesicle and a mitotic division. The auxospore envelope is discarded, and the size is regenerated to the species maximum cell size.

Figure 4. Life cycle of the radial centric diatom *Stephanodiscus* undergoing oogamous reproduction adapted from Round et al. (1990). 1-2) A vegetatively reproducing cell enters mitosis and develops siliceous hypotheca valves within the parent cell. The process begins near the nucleus and extends in both directions until completion. 2-3) Vegetative reproduction continues and cell size reduction occurs. The top sequence shows the fate of the original epitheca, which remains the same size, and gives rise to daughter valves of the same size class with each mitotic division. The bottom sequence shows the fate of the hypotheca, which produces smaller cells with each division, and ultimately gives rise to smaller daughter valve sizes than those derived from the epitheca. 4-5) Sexual reproduction begins when cells reach the critical size threshold and come into close proximity with one another. Each cell differentiates into either two non-motile cells (eggs) or several motile flagellated cells (sperm). 6) The frustules of sexualized cells open at the girdle bands and release the gametes. 7) Upon fertilization, the new cell swells to become the auxospore and becomes enveloped by a circular siliceous coat. One set of parental valves remains attached to the outside of the auxospore. Within the auxospore a new size regenerated cell is formed with the formation of two new epitheca valves. 8) The auxospore then splits into two hemispherical daughter valves. Within each valve, a new hypotheca valve forms to complete the frustule and the siliceous hemisphere is discarded. 9-10) The size-regenerated cells form new girdle bands between the epitheca and hypotheca, which allows the cell to expand and resume vegetative reproduction.

Most raphid diatoms, however, experience a different sexual process, in which two diatom cells generate gametangia (structures similar to those that house gametes in bryophytes) instead of gametes. An important feature of this form of reproduction is that because raphid diatoms are motile, the cells move toward one another to facilitate fertilization, instead of relying on motile gametes. Once the cells come into close proximity, each cell undergoes meiotic division, to produce four haploid nuclei. Three of these nuclei degenerate and the remaining nucleus

becomes the gametangium. The haploid gametangia are then transferred from one cell to another via copulation through a tunnel of protoplasm that connects the cells through the girdle bands (Drebes 1977). The cell then swells to create the primary auxospore wall (organic, well defined cell wall), which splits equatorially and persists as two caps on the ends of the now elongating auxospore (Figure 4; Trobajo et al. 2006). As the auxospore of pennate diatoms expands, a thin membrane called the perizonium is deposited as a set of organized bands both transverse and longitudinal appearing almost like siliceous scales that cover the mature auxospore (Trobajo et al. 2006). The zygote forms the new size-regenerated epitheca and hypotheca valves and the auxospore envelope is discarded. The cells then resume vegetative mitotic division until they again reach the critical size threshold and the entire process repeats.

Diatoms not only differ in the mechanism by which gametes are produced, or the process of zygote formation, but also in the reproductive capability of their gametes/gametangia. Some diatom species are homothallic and are capable of producing both male and female gametes/gametangia within the same individual. Other species are heterothallic, and generate either male or female gametes/gametangia, which requires another individual of the opposite mating type with which to mate (similar to + and - mating types observed in some fungi). Although the events described above represent the general reproductive events and strategies in diatoms, within each of these two general groupings several variations of these strategies also exist (see Geitler 1935 for a detailed description).

STUDYING SPECIATION IN DIATOMS

One of the greatest challenges to studying diatom speciation is understanding what constitutes a clear delimitation among diatom species. Although all speciation researchers face this consideration, it has posed a formidable problem to studying speciation in this group as the range in the number of estimated extant species of diatoms attests. Consequently, for most of the history of diatom research, discussion of speciation has focused largely on classifying diatom species, and only relatively recently have researchers begun to address questions that focus on the *process* of speciation. Species concepts and definitions have been reviewed thoroughly as applied generally to multicellular eukaryotic taxa (Hey 2001; Coyne and Orr 2004) and how these definitions apply to microeukaryotes has also been discussed at length (Mann 1989; Theriot 1992; Mann 1999; Amato 2010). Most of the arguments made to emphasize the benefits of employing one species concept or definition over another have strengths and weaknesses with regard to providing a framework in which to study speciation and we will not repeat these arguments here. Instead, we briefly discuss two species concepts in particular, that when used together, we feel provides the best framework for understanding the mechanisms that are important for speciation in diatoms.

Identifying species is, of course, necessary to study the processes by which species form. Because the exterior of the frustule is ornately decorated with striations, pores, spines, crevices, etc., it provides several characters that can be used to categorize individuals into distinct species. Beginning with the earliest diatomists, external morphology (Van Heurck 1896) or other biological characters such as the mechanism of auxospore formation (Geitler 1935) have been the primary methods used for assigning species status— thus, species status has predominantly relied on the Morphological Species Concept (MSC) in diatom taxonomy.

However, the structural variation observed among groups of diatoms to delineate species becomes problematic to studying speciation for two reasons. First, there are no clear criteria to establish what degree of morphological differences is necessary and sufficient to define good species. This is a general limitation of the MSC (Coyne and Orr 2004), but is particularly problematic given the subtle, but frequent, ultrastructural differences among diatom taxa (Mann 1981, 1984; Theriot 1987; Pappas and Stoermer 2001; Shimada et al. 2003; Mann et al. 2004). Although frustule morphology does appear to have high heritability (Mann 1984; Mann 1989; Mann et al. 1999; Evans et al. 2007; Evans et al. 2008; Trobajo et al. 2010), intraspecific variation in morphology has made species groups difficult to define. Second, the unique life cycle and life history of diatoms makes categorizing diatom species using morphology alone difficult. The reason is that many diatoms possess the diplontic life cycle discussed above: they experience asexual, vegetative reproduction punctuated by regular generations of sexual reproduction. During the progression through the vegetative phase, diatoms experience a reduction in size. As a consequence, external morphological features (*e.g.*, number of pores, striation pattern) change and can differ dramatically in both size and shape (Figure 3). To further complicate matters, the appearance of Janus valves, a phenomenon whereby the epitheca and hypotheca form different morphological patterns between consecutive cell divisions, also has the potential to obscure species boundaries in mixed populations. Although the reason for the occurrence of Janus valves is unknown, the result is clear: individuals of the same species may appear as individuals that belong to separate species (Stoermer 1967; McBride and Edgar 1998). As a consequence of these two biological phenomena, individuals within the same species may appear morphologically different, and individuals of different species may appear morphologically identical when categorized on the basis of external morphology alone (Kocielek and Stoermer 2010). This has given rise to considerable uncertainty in species delimitation, prompting many researchers to delineate a myriad of varieties and so-called phenodemes instead of what might be considered good species (Mann 1999).

Perhaps the most important limitation of the MSC for studying speciation in diatoms, is that although the MSC may provide some guidance to identifying what species are, it makes no predictions on how species evolve (Coyne and Orr 2004). For this reason, many diatomists have considered the Biological Species Concept (BSC) more useful to understand the process of speciation (Mann 1999; Amato 2010). At its core, the BSC defines species as groups of interbreeding organisms that are reproductively isolated from other groups of interbreeding organisms (Mayr 1942, 1963). The BSC is not without its limitations, one of which is the problem of applying such a definition to completely allopatric populations, but it does offer a clear advantage to understanding the speciation process (Coyne and Orr 2004): when we understand the evolution of RI, we begin to understand the process by which new species evolve. Although the extent of sexual reproduction among diatom taxa remains unclear, some diatoms do experience a routine sexual phase as a crucial part of their life cycle to restore cell size. Thus, the possibility exists for hybridization and gene flow among co-occurring diatom populations in the absence of any barriers to reproduction, particularly if these populations experience their sexual reproductive stage at the same time. It is also important to mention that although external morphology alone has limitations for defining diatom species, with regard to understanding the speciation process, differences in morphology do appear to make some contribution to restricting gene flow between some diatom populations (discussed below). For these reasons, we propose that to understand speciation in diatoms, both the evolution of

morphology and the evolution of RI need to be considered to fully investigate the speciation process.

PATTERNS OF SPECIATION IN DIATOMS

Marine Records

Marine diatom fossils occur early in the fossil record with the first reported appearance of recognizably diatom-like cells dating to the Jurassic period 175 million years ago (Myr) (Rothpletz 1896). However, this claim has been impossible to verify as the particular fossil material was lost during the bombing of Berlin in World War II along with many other scientific collections (for a historical account of this incident, see Falkowski et al. 2004). The first well-documented diatom fossils date to the Upper Cretaceous (Harwood and Nikolaev 1990), at which time diatoms appear to have already evolved considerable diversity. Diatoms during this time appear to have been either solitary or formed chains with long spines to possibly increase drag and remain in the photic zone where plankton are abundant. Recent studies of diatoms show that buoyancy can be achieved in this manner: some extant species can produce chitin threads that extrude from strutted processes on the valve, which extend outward and increase buoyancy, or can connect cells to form strings of diatoms (Durkin et al. 2009).

Molecular studies using biostratigraphic markers of unambiguous diatoms and ancient fossil lipids indicative of particular diatom lineages (*e.g.*, rhizosolenioid diatoms (Damsté et al. 2004)) suggest an origin of the group around the Permian/Triassic extinction event (Kooistra and Medlin 1996; Medlin et al. 1997). Due to the highly alkaline conditions of seawater at increasing depths and marine biochemical cycles that occur due to diagenesis of marine sediments, pre-Cretaceous intact diatom fossils are rare because silica dissolves with increasing depths and often completely degrades. The same phenomenon has been observed in the contemporary Arctic/Antarctic Oceans due to production in nutrient rich upwellings (Sarmiento et al. 2004). Moreover, when diatom fossilization does occur, although mineral replacement with pyrite leaves the general diatom cell shapes intact, it often obscures the finer details of frustule morphology. Without the fine ultrastructure, genus or even species assessment is limited to only the valve outline. The fossil record is also skewed toward species that produced heavily silicified frustules or resting spores— a dormancy strategy in which large amounts of silica are deposited onto the valve, or additional valves are formed within the parent frustule to survive abiotic stresses. This ultimately creates gaps in the fossil record for some species and makes the biostratigraphic origin of species that are lightly silicified (which includes many recent genera) difficult to assign. However, renewed interest in diatom micropaleontology has begun to fill in some of these gaps for parts of the diatom Tree of Life (Chacon-Baca et al. 2002; Harwood et al. 2004; Singh et al. 2006; Witkowski et al. 2011). Re-examination of previously published records would also prove useful to verify the origin of genera that have recently undergone taxonomic splitting, as well as discovering deposits aged between the ambiguous Jurassic record and the first unambiguous Cretaceous record to help fill any remaining gaps.

It also appears from the Upper Cretaceous fossil record (with support from molecular phylogenies) that diatoms are ancestrally marine and planktonic, are thought to have first evolved with a radially symmetric cell shape and little to absent motility, and show a directional

trend toward elongate shape and motility (Alverson et al. 2006; but see Harwood et al. 2004 for a potential terrestrial origin of diatoms in shallow ephemeral pools). Another major trend in diatom evolution was from a purely planktonic existence to a close association with a substrate that required the evolution of motility and/or attachment. Motility on a substrate is made possible by the raphe (Figure 3A), which appears as a longitudinal fissure on the valve face (epitheca/hypotheca) of one or both valves; motility is achieved via actin/microtubule-based movement through gaps in the raphe (Edgar and Pickett-Heaps 1983; Poulsen et al. 1999). The evolution of the raphe generally seems to be an adaptation to sediment burial and perhaps a strategy to access buried nutrients such as nitrate/nitrite fixed by bacteria. Several studies have also shown that the raphe is important in maintaining diurnal movement of sediment-associated diatoms such as *Pinnularia* that migrate to the surface of pond sediment toward the light before midday by phototaxis, and then bury themselves before the high light part of the day (Harper 1976). Raphe also allow diatoms in the genus *Hantzschia* to respond to other environmental change such as emerge when the tide recedes and bury themselves prior to flooding (Kingston 1999).

Species diversity from the Jurassic to the Cenozoic appears to have remained largely unchanged with the addition of only few new genera (Sims et al. 2006). It appears that diatoms were also one of the few groups that seem to have survived relatively unscathed by the Cretaceous/Tertiary (*i.e.*, KT Boundary) mass extinction. Studies of Ocean Drilling Project cores and terrestrial deposits of marine origin suggest that diatom diversity increased throughout the Cenozoic with two bursts of rapid diversification during the Eocene/Oligocene and one at the middle to late Miocene (Falkowski et al. 2004). However, this initial pattern might reflect a biased sampling of those fossil sediments that were more commonly exposed during sampling. Rabosky and Sorhannus (2009) provide a different estimate that suggests marine diatom biodiversity reached its highest level between the Eocene and Oligocene (35-30 Myr), then decreased dramatically during the late Oligocene, and subsequently rose to half the maximum observed during the late Eocene. Falkowski et al. (2004) also suggest that the pattern of increasing diatom biodiversity follows a trend with the diversification of grasses during the Miocene. They hypothesize that this correlation is potentially tied to the increased dissolution of terrestrial silica from soils by grass that would introduce greater amounts of silica into estuaries (oceans are typically silica-limited), which might have allowed diatoms to diversify. However, the strength of this relationship is unclear, as the analysis performed by Rabosky and Sorhannus (2009) shows no correlation between grassland expansion and diatom diversity.

Evidence of speciation events in the fossil record of marine diatoms has been carefully examined in only a few examples. These studies typically focus on the biostratigraphy of species in ocean drilling core records and use a strict analysis of transitions in morphology to infer speciation events. Koizumi and Yanisagawa (1990) characterized the evolution of *Pseudoeunotia dolious* from oceanic core records east of Japan, and observed a gradually increasing convex dorsal margin (asymmetrical form) from a species with *Nitzschia fossilis*-like morphology (strictly bilateral and symmetrical form) that appeared to coincide with climatic deterioration during the Pleistocene. However, this apparent speciation event does not correspond precisely with the climatic deterioration during the Pleistocene and the authors speculate that development of the convex dorsal margin is likely the result of adaptation to some other factor(s) (Koizumi and Yanagisawa 1990). They also claim that *N. fossilis*, the presumed ancestor of *P. dolious*, was once abundant in North Pacific during the Pliocene, but was rapidly replaced by *P. dolious* over the course of roughly 600,000 years. Koizumi and

Yanisagawa hypothesize that *P. dolious* evolved its characteristic morphology at the beginning of the Pleistocene when surface water temperature decreased, and they observe increased asymmetry in younger and younger core layers. Curiously, the occurrence of *P. dolious* is slightly earlier in the lower latitudes (2.0 Myr) than in middle latitudes (1.89 Myr). Although this study presents some potentially interesting patterns of speciation between these two species, the results provide only suggestive evidence of the evolutionary relationships between these two taxa, and are based strictly on phenetic similarity. It is plausible that *P. dolious* is simply a morphological variant of *N. fossilis* and not a distinct species. But, if these two populations do represent an example of anagenesis in the fossil record, then the tempo of speciation (as well as morphological evolution) in marine diatoms appears slow, at least in this case, as 10^6 years pass before complete replacement of *N. fossilis* by *P. dolious* occurs.

Another example of speciation in the marine paleontological record comes from the genus *Rhizosolenia*, in which a cladogenetic event that occurred around 3.2-3.1 Myr (end of the Pliocene) gave rise to two modern diatom lineages *R. praebergonii* and *R. bergonii* in the Pacific Ocean (Sorhannus et al. 1988). An examination of core records shows that *R. praebergonii* and *R. bergonii* split from their common ancestor and experienced different amounts of morphological evolution. In particular, *R. bergonii* appears to have retained a morphology that is closer to that of the ancestral form, whereas *R. praebergonii* appears to have experienced substantial morphological evolution. It also appears that the tempo of morphological change fluctuated dramatically over time: *R. praebergonii* began to diverge gradually from *R. bergonii* in the Pacific Ocean around 3.1 Myr, then appears to have experienced several bursts of morphological evolution leading to its present morphology (Sorhannus et al. 1988).

R. praebergonii first appears in cores sampled from the Equatorial Pacific, and co-occurs with *R. bergonii*. Two possible scenarios have been offered to explain speciation events in *R. praebergonii* based on patterns observed in core samples obtained from locations around the Pacific (Sorhannus et al. 1988; Sorhannus 1990). First, the appearance of *R. praebergonii* might represent a potential case of localized sympatric speciation, followed by rapid dispersal throughout the Pacific region. Second, parallel cladogenetic events might have occurred over the entire range of the Equatorial Pacific to give rise to new species. Sorhannus (1990) favors the sympatric speciation-migration scenario over parallel allopatric speciation, and reasons that because *R. praebergonii* shows little variation in morphology it seems less likely the species experienced multiple independent cases of morphological evolution. He also suggests that one possible mechanism that might have given rise to the pattern observed in the marine record is size-selective predation and anti-predation adaptation that decreased cell size, as core records show that the length of the apical spine possessed by these species decreased in length in *R. praebergonii* over time. These subtle changes in valve morphology with rapid decreases in cell size in *R. praebergonii* followed by stasis were consequently interpreted as a rapid transition across an adaptive valley to a new adaptive peak. However, little historical or contemporary evidence exists for even a suggested anti-predator or grazing pressure on these species. In fact, if the absence of predation pressure drove the evolution of morphology, its effects should also be observed in *R. bergonii*, yet this species shows little change in apical spine length compared to the ancestral form. Experimental studies with modern *Rhizosolenia* taxa could prove informative for testing the possible selective advantage of shorter versus longer apical spines (with longer spines increasing drag, reducing sinking potential) to grazing pressure. Adaptation to predation represents only one possible explanation for the morphological change in *R.*

praebergonii, as many environmental factors are known to influence the silica morphology of diatom species, such as changes in salinity (Schultz 1971; Tuchman et al. 1984; Saros and Fritz 2000; Trobajo et al. 2011), silica availability (Finkel et al. 2010) and nutrient availability (Theriot et al. 1988b).

A third morphologically distinct *Rhizosolenia* species, *R. sigmoida*, also appears to have evolved from a *R. bergonii* ancestor, and all three species coexisted briefly (Sorhannus et al. 1991). Interestingly, *R. sigmoida* is found only in the ocean drill core taken from the coast of Peru, and disappears around 3.13-3.07 Myr after persisting for just 60,000 years. Sorhannus et al. (1991) suggest that the environmental factors around coastal Peru at that time (cooler waters, greater range of salinity and central equatorial water mass) may have driven adaptations that ultimately provided barriers to gene flow among populations of *R. bergonii*. They also speculate that the disappearance of *R. sigmoida* may have been the result of either competitive exclusion for some nutrient/resource that ultimately led to extinction, or that *R. sigmoida* might have hybridized and merged with either one or both of its two sister taxa.

Freshwater Records

Although most paleontological work has focused on marine sediments, some data do exist that describe patterns of speciation in freshwater diatom taxa. Lake Baikal, one of the Earth's oldest (approximately 20 Myr; Mackay 2007) and largest freshwater lakes, provides a detailed diatom history revealed in sediment core samples (Mackay et al. 1998; Khursevich et al. 2001; Khursevich et al. 2002; Khursevich et al. 2005; Mackay 2007). Baikal lake cores detail dramatic and long-term changes in the lake's diatom community structure over time, which include several species appearances followed by their subsequent extinctions. In particular, the record chronicles the evolution of centric diatoms associated with processes of extinction and renewal that appears closely associated with periods of global climate changes (Khursevich et al. 2000). Lake Baikal's fossil record is also unique in both the age and preservation, which has provided a high temporal resolution for studying the evolution of freshwater centric diatoms. The lake's well-dated sediments and long geological record have thus allowed researchers to designate biostratigraphic zones carefully defined by the appearance, abundance, and extinction of particular diatom genera or species (Khursevich et al. 2001; Khursevich et al. 2005). For example, the sediment zones that belong to the Late Miocene-Early Pliocene periods show the appearance, speciation, and extinction of the genus *Mesodictyopsis*, a genus found only in the Lake Baikal (Khursevich et al. 2004). The Pliocene epoch sediments are characterized by the appearance, speciation, and extinction of another endemic genus, *Stephanopsis*.

The Pleistocene epoch sediments are also further distinguished by the appearance and active speciation within the genus *Stephanodiscus* (Khursevich et al. 2004). Throughout its 5 million year history, Lake Baikal has been home to more than 21 species of *Stephanodiscus* (Khursevich et al. 2000; Khursevich et al. 2005). The diatom flora of Lake Baikal experience frequent solar insolation fluctuations caused by the 23,000 and 43,000 cycles of the Earth's precession and obliquity (Khursevich et al. 2001; Karabanov et al. 2004). Changes in global ice volume also have a substantial impact on local precipitation, which gives rise to increases in nutrient loading and terrestrial inputs during wetter years, and decreases in nutrient availability that leads to stratification or earlier ice-out resulting in higher productivity during drier years. This close relationship between the global and local aquatic environments is one of

the many reasons diatoms are, and have been, used to track changes in water chemistry for paleolimnology, water quality, and general ecosystem perturbation (Smol et al. 1986; Dixit et al. 1992; Stevenson and Pan 1999; Potapova and Charles 2002, 2003, 2007; Smol and Stoermer 2010; Potapova 2011). Because diatom species are particularly sensitive to alternating environmental conditions, these fluctuations provide permissive conditions that have the potential to drive periods of rapid speciation or extinction.

The rapid appearances and extinctions of *Stephanodiscus* species, in particular, are thus likely linked to the pronounced periods of solar insolation that might have occurred as a consequence of the rising of the Tibetan Plateau in the Late Miocene-Early Pliocene (Khursevich et al. 2000). Khursevich et al. (2000) suggest the rapid speciation in the genus was also the result of frequent changes in climatic conditions during a period of alternating warming and cooling phases. These temperature phases were the product of Siberian glacial expansion and retreat that affected the temperature of the region. Lake Baikal's five million year old record of diatom biostratigraphy and long climatic cycles suggests a coupling of speciation events to these erratic climatic conditions. Reorganizations of the diatom communities coincide with the climate changes that alter the lakes abiotic conditions through increases or decreases in nutrient availability, light, water column mixing, temperature, and periods of ice cover could preferentially select for differential survival and reproduction of diatom clonal lineages.

REPRODUCTIVE ISOLATION

Much of what evolutionary biologists have learned about the processes that give rise to speciation has come from studying several reproductive isolating mechanisms originally described by Dobzhansky (1937, 1951). These include barriers to gene flow that might exist between two populations that act either before fertilization (prezygotic isolation) or after fertilization (postzygotic isolation). Among the marine and freshwater species of diatoms where RI has been studied, both forms of RI are observed. Although prezygotic barriers appear more common in preventing gene flow than postzygotic barriers, it is difficult to estimate the importance of postzygotic isolation because in most of these cases prezygotic isolation is complete, which precludes the possibility of studying fertilization defects, or generating interspecific F_1 hybrid individuals. Two interesting patterns of RI are also emerging from recent studies. One pattern is that it appears considerable polymorphism for RI exists and segregates within previously defined species groups, similar to observations made among populations of some multicellular eukaryotic species (Takahashi et al. 2001; Sweigart et al. 2007; Good et al. 2008; Reed et al. 2008; Yukilevich and True 2008; Nolte et al. 2009; Vyskočilová et al. 2009; Lachance and True 2010; Martin and Willis 2010; Teeter et al. 2010; Kozłowska et al. 2012). (Caution is needed in this interpretation, however, as this might simply reflect the nature of species definitions in diatoms.) The other emerging pattern is that cell morphology seems to play an important role in contributing to RI in some cases, which suggests that understanding the evolution of cell morphology could be important to understanding speciation in diatom taxa.

Mate Discrimination

Among co-occurring diatom populations, conspecific mate recognition mechanisms within species or demes (varieties) within species appear common in preventing hybridization. Indeed, the results of crosses between morphologically dissimilar diatoms were first recorded beginning in the late 1950's by Geitler who observed that hybridization failed to occur in many of these cases (Geitler 1958a, 1958b, 1975). The first quantitative experiments to test premating isolation in diatoms were made by crossing sympatric populations of *Navicula pupula* (current taxonomic designation of this species is *Sellaphora pupula*) and *Amphora ovalis* that inhabit Blackford Pond in Edinburgh, Scotland (Mann 1984). Mann (1984) studied the pairing that occurs during the sexual phases among four morphologically distinct phenodemes of *S. pupula* (phenodemes 1-4) and two morphologically distinct varieties of *A. ovalis* (var. *affinis* and var. *pediculus*). Populations of each phenodeme or variety were induced to enter the sexual phase of the lifecycle by adjusting the environmental conditions in the laboratory (diatom cells that have entered the sexual reproduction life stage are hereafter referred to as "sexualized"), and upon sexualization, auxosporulation became synchronized, which allowed for crosses among the different populations to be performed. When the sexualized populations were mixed together, pairing between individuals from the same phenodeme or variety would occur readily. However, pairing was never observed among sexualized individuals when crosses were performed between different phenodemes of *S. pupula* or different varieties of *A. ovalis*.

A lack of pairing among morphologically distinct demes has also been observed in interdeme crosses of the freshwater diatoms *S. pupula* and *S. laevissima* (Behnke et al. 2004). Behnke et al. (2004) studied 11 strains of freshwater *S. pupula* and 2 strains of the closely related species *S. laevissima*. Morphologies observed among the *S. pupula* demes fell into three categories: a "rectangular" morph, which is longer and more robust than the shorter, more slender "capitate" and "pseudocapitate" morphs, and a "small" morph, which possesses a much reduced cell size compared to the rectangular and capitate/pseudocapitate morphs. The two *S. laevissima* demes both differ in size and striation patterns compared to all three *S. pupula* demes. Premating RI was observed when interdeme crosses were performed among several demes; in each cross individual cells failed to form pairs required to exchange genetic material. Interestingly, in contrast to the crosses performed among the *S. pupula* and *A. ovalis* demes, cell morphology in these experiments was not a good indicator of pairing capability, as sexualized demes that possessed similar morphologies would sometimes fail to pair, whereas demes with different morphologies would sometimes pair. These results show that premating barriers have evolved in the absence of any substantial morphological evolution within *Sellaphora*.

However, in some diatom taxa morphology does appear to have a large effect on preventing mating. Mann and Chepurinov (2005) observed sexual pairing in three demes of the freshwater raphid diatoms that belong to the *Neidium ampliutum sensu lato* complex: *N. iridis*, and two morphologically distinct demes of *N. ampliutum*, which contains a "major" deme and "minor" deme that differ on the basis of cell size and frustule striation density. The major deme is characterized by wider frustule sizes and less dense striation patterns compared to the minor deme. Mating within these demes occurs when sexualized individuals pair and orient themselves so that they align girdle-to-girdle, which allows fertilization to occur. Interactions in mixed populations of *N. ampliutum* and *N. iridis* never resulted in attempted pairing. In the *N. ampliutum* phenodemes, mating and auxospore formation occurred in crosses within both

the major and minor demes of *N. ampliatum* provided that individuals were a mix of opposite mating types. However, crosses in mixed populations of individuals from the major and minor demes failed to align correctly and never appeared to mate. In particular, pairing between a major cell and a minor cell was observed only three times in mixed populations. In each of these cases there was no conclusive evidence that fertilization had occurred. Interestingly, the strength of mating preference on the basis of cell size appears to be different between the two demes. Individuals that belong to the major deme would mate readily with other major cells even when their cell sizes were considerably different, but individuals that belong to the minor deme preferentially pair with other minor deme cells if they were similarly sized. Although this suggests that mate discrimination on the basis of cell size might operate within the *N. ampliatum* minor deme, this result might be an artifact of cell size required to enter the sexualized reproductive stage, as sexualization in the minor deme becomes more frequent as cells become smaller (Mann and Chepurinov 2005).

Because diatoms lack any developed visual sensory system, the existence of apparent mate recognition systems suggests that diatoms secrete chemical cues into the surrounding water column to attract potential mates. Recent work has begun to dissect the nature of these signals. Sato et al. (2011) studied sexual reproduction in araphid pennate diatom *Pseudostaurosira trainorii*, which produces motile male gametes and immotile female gametes. Motility of the male sperm is generated by extrusion and retrieval of microtubules through pores in the frustule. Through a series of elegant experiments that paired vegetative and sexualized individuals of each sex, Sato and colleagues demonstrated the existence of both male and female sex pheromones that act to guide fertilization. Sexual reproduction begins when vegetative females secrete ph-1 pheromone, which induces sexualization in males. Males then release their gametes, and the sperm cells explore the nearby area by swimming in a random walk. Once induced, sexualized male cells also secrete the ph-2 pheromone, which stimulates sexualization of vegetative female cells in the nearby area. The sexualized female cells then direct fertilization when they secrete a putative ph-3 pheromone, which results in directed ameboid movement of sperm toward the female's eggs. Thus, the possibility exists that divergence between sex pheromones and their recognition systems might give rise to species-specific pheromonal cues and cause RI.

Temporal Isolation

Differences in the timing during which some diatoms enter the sexualized life stage also act to limit gene flow between species. Two closely related centric diatoms *Aulacoseira skvortzowii* and *A. baicalensis* reside in Lake Baikal and experience environmentally driven differences that govern the timing of their respective life stages (Jewson et al. 2008; Jewson et al. 2010). Many diatom lineages have an additional component to their life cycle that involves the formation of resting spores or resting cells used to survive unfavorable environmental conditions (McQuoid and Hobson 1996). Both mechanisms operate much like dormancy in vascular plants by enabling bet-hedging population emergence and differential survival of lineages (Finch-Savage and Leubner-Metzger 2006). Resting cells are physiologically dormant cells that are packed with reserve nutrients, whereas resting spores are characterized by a thickening of the siliceous wall causing the cells to sink to greater depths or to sink out of the water column (Sicko-Goad et al. 1986; Sicko-Goad and Andresen 1991; Edlund et al. 1996). It

is thought that resting spore formation is the ancestral state in diatoms, and might also function as a survival mechanism against desiccation, grazing, and dissolution (Hargraves and French 1983). Environmental factors such as light limitation, nutrient depletion, or changes in temperature can act as triggers to initiate resting dormancy strategies (McQuoid and Hobson 1996).

A. skvortzowii and *A. baicalensis* both produce resting cells, however only *A. skvortzowii* produces thick resting spores as a perennation strategy (Jewson et al. 2008; Jewson et al. 2010). *A. baicalensis* grows in the pelagic zone of Lake Baikal under the January ice until May/June when it forms resting cells as the lake water becomes stratified due to warmer summer temperatures. *A. baicalensis* resting cells contain high concentrations of nutrients required to survive at lower lake depths. However, due to silica dissolution with increasing lake depth, this diatom also experiences a physiological trade-off as a consequence of resting cell formation by increasing wall thickness to reduce risk of dissolution at the expense of decreasing cell volume and limiting nutrient reserves (Jewson et al. 2010). *A. skvortzowii*, which resides nearshore and at thermal bar regions within the water column, appears in the plankton from May until early autumn. Due to reduced light during autumn-winter, *A. skvortzowii* produces resting spores in response to the reduction in phosphate concentration during summer. The spores sink to an intermediate depth of ~50 meters where they may persist until the next spring water strata overturn.

During late May to early June before stratification of the lake, phosphate levels drop below 6 µg/L as a consequence of the increase in picoplankton growth (Nagata et al. 1994; Belykh and Sorokovikova 2003; Fietz et al. 2005). In *A. skvortzowii*, the decrease in phosphate concentration induces resting spore formation in individuals that have cell diameters that exceed 10 µm. However, for smaller cells, the drop in phosphate concentration induces auxosporulation, and consequently an increase in cell size, before resting spore formation (Jewson et al. 2008). In contrast, *A. baicalensis* forms resting cells in early to mid-June when water temperatures in the south basin exceed 6 °C. Auxosporulation in this species occurs between February and April while a sheet of ice still exists on the lake surface, thus preventing these two species from interbreeding.

F₁ Hybrid Sterility and Inviability

Because premating isolation is complete between many species of diatoms that have been studied for RI, studying the frequency and the importance of postzygotic isolation has been difficult. However, in the handful of cases where prezygotic isolation is incomplete, it appears that postzygotic isolation also exists as a barrier to gene flow between species. Because of the nature of the diatom sexual reproduction, it is difficult to separate intrinsic postzygotic isolation into F₁ hybrid sterility and F₁ hybrid inviability: viable F₁ hybrids ultimately die if they are sterile because they are unable to form auxospores. An example of this is observed in crosses among demes of *Eunotia bilunaris sensu lato* species complex isolated from freshwaters in Belgium where two particular demes, the "slender" and the "robust" demes, show strong postzygotic isolation (Vanormelingen et al. 2008). Crosses within each deme proceed easily, but interdeme crosses are considerably more difficult to perform (~20–400 times less frequent), although not impossible. Vanormelingen and colleagues observed that these crosses between slender and robust individuals often need to be repeated to obtain F₁ hybrid progeny due to lack

of sexual activity, which suggests that pheromonal cues might govern mating in these species. Crosses within each deme resulted in pairing and the production of F₁ hybrid individuals that formed healthy auxospores. In contrast, only 12 interdeme F₁ hybrids were obtained, and 9 of 12 ceased vegetative reproduction after a few mitotic divisions and died (Vanormelingen et al. 2008).

Postzygotic isolation also appears to act between populations of some marine diatoms. Amato et al. (2007) collected 95 strains of *Pseudo-nitzschia* genus from the Gulf of Naples. Their collection included several isolates of six different species: *P. delicatissima*, *P. pseudodelicatissima*, *P. dolorosa*, *P. cuspidata*, *P. calliantha*, and *P. cacialantha*. Because these demes are difficult to distinguish morphologically (many external characters overlap among the groups), they were classified using characteristic DNA sequence variation at the ribosomal Internal Transcribed Spacer 2 (ITS-2) locus, which proves to be a good indicator of deme identity. For the majority of demes, sexualization could be induced and crosses within demes occurred readily and produced viable, fertile F₁ progeny. Most interdeme crosses resulted in no sexual reproduction due to the failure of cells to pair. In crosses between two demes of *P. calliantha*, however, prezygotic isolation was incomplete and F₁ individuals were obtained, but failed to develop into auxospores and consequently died (Amato et al. 2007).

THE GENETICS OF REPRODUCTIVE ISOLATION

Dissecting the genetic basis of RI in diatoms is a burgeoning field. Although they are usually not considered to be model genetic organisms, the availability of both modern molecular techniques and genome sequence data (Armbrust et al. 2004; Bowler et al. 2008) are promising developments for beginning to understand speciation at the molecular level in the microeukaryotes. Much of the work on the genetics of speciation in diatoms has thus far focused on divergence at the ribosomal ITS-2 locus as an indicator of reproductive compatibility (Coleman 2009). ITS-2 sequences are often used to assign diatoms to demes or varieties within species (*e.g.*, Amato et al. 2007) or construct diatom phylogenies (*e.g.*, Godhe et al. 2006; Evans et al. 2007; Härnström et al. 2011). ITS-2 sequences also appear to correlate with the degree of RI observed among populations: demes that possess similar ITS-2 sequences will mate and produce viable, fertile offspring and those with increasingly divergent sequences fail to mate (Behnke et al. 2004; Amato et al. 2007). Although the ribosomal ITS RNAs are required to construct ribosomal subunits, they are not required for the function of mature ribosomes (Tschochner and Hurt 2003; Staley and Woolford Jr 2009). Because it provides important functions for viability, it might be reasonable to speculate that in interspecific hybrid genotypes, divergence at the ITS-2 locus could give rise to incompatible epistatic interactions that are a common cause of postzygotic hybrid incompatibilities (Dobzhansky 1937; Muller 1942; Coyne and Orr 2004). However, it is unclear exactly how potential incompatibilities involving ITS-2 would give rise to *prezygotic* isolation observed in crosses (Behnke et al. 2004; Amato et al. 2007). One possibility is that postzygotic isolation via incompatibilities involving ITS-2 might evolve early during diatom speciation, followed by reinforcement that drives the evolution of premating isolation. At the current level of resolution, however, it is difficult to ascertain whether the pattern of evolution observed at ITS-2 is a cause or a consequence of

divergence between populations, and whether ITS-2 RNA is involved in any hybrid incompatibilities.

Another set of potential candidate genes that might cause RI are members of the *Sexually induced gene* (*Sig*) family that were first identified in the centric diatom *Thalassiosira weissflogii* (Armbrust 1999). *Sig1*, *Sig2*, and *Sig3* are all transcriptionally upregulated within a few hours after entry into the sexual reproduction phase of the life cycle, immediately preceding gamete formation. Molecular sequence analysis shows that each of the *Sig* genes encodes a protein with a putative hydrophobic signal sequence, but lacks long stretches of hydrophobic residues, which suggests that *Sig* proteins are likely secreted rather than membrane-bound. The predicted protein sequence also possesses several epithelial growth factor-like domains and bears strong similarity to vertebrate matrix glycoprotein tenascin X, an extracellular matrix (ECM) protein known to be functionally important for mediating cell-cell interactions (Armbrust 1999). It has thus been hypothesized that the *Sig* proteins could be important during gamete recognition and/or fusion. Consistent with patterns of molecular evolution observed at other genes known to mediate sperm-egg interaction and cause RI between species (Vacquier and Swanson 2011), *Sig1* also shows molecular signature of positive selection among *Thalassiosira* species (Armbrust and Galindo 2001; Sorhannus and Kosakovsky Pond 2006), but shows no signature of positive selection among *T. weissflogii* isolates (Suzuki and Nei 2004). Although the *Sig* proteins could prove important for fertilization success and cause RI as a byproduct of divergence between species, further work is needed to determine if these proteins localize to the ECM of the gametes themselves and whether they do indeed function during sperm-egg attraction or interaction.

Whole genome duplication and polyploidy may also prove to be important genetic mechanisms of speciation similar to what is observed for speciation in higher plants (*e.g.*, Soltis et al. 2009). Indeed, variation in ploidy level might be fairly common among diatoms: triploid and tetraploid lineages have been identified in several pennate diatom genera (Mann and Stickle 1991; Mann 1994; Chepurnov and Roshchin 1995). Studies of the marine planktonic diatom *Ditylum brightwellii* suggest that large-scale genomic changes such as these might contribute to rapid diversification between populations. Koester et al. (2010) examined three populations of *D. brightwellii* and quantified differences in genome size: one population was sampled from Akaroa Harbor in New Zealand, and two different populations (population 1 and population 2) were sampled from Puget Sound, Washington in the United States. Flow cytometry estimates indicate that although no significant differences in genome size exist between the isolate from New Zealand and population 1 from Washington, population 2 from Washington shows a roughly two-fold increase in genomic DNA content compared to the other two populations (Koester et al. 2010). Sequence comparisons of ITS-1 also show no difference between New Zealand and population 1, but characteristic differences at ITS-1 exist between populations 1 and 2. This result is also consistent with high F_{st} values between Washington populations 1 and 2, which indicates that limited gene flow occurs between them (Rynearson et al. 2006). Although the authors did not perform any laboratory crosses among these populations, comparisons of growth rates and cell sizes among the populations suggest that population 2 might be reproductively isolated from both population 1 and the New Zealand population. In particular, Washington population 2 possesses a larger cell size and slower growth rates, which suggests the possibility that the timing of sexual reproduction in population 2 might differ considerably from that of population 1 or from the New Zealand population.

DIATOMS: A MODEL SYSTEM TO STUDY THE CONSEQUENCES OF CLIMATIC CHANGE ON SPECIATION

As discussed above, diatoms are acutely sensitive to changes in their environment, and environmental change appears correlated in some cases with speciation events in the fossil record. Understanding how changes in the environment give rise to the evolution of RI therefore seems to be an important factor for understanding speciation in diatoms. Research efforts using both extant marine and freshwater species have added to our understanding of how environmental differences can give rise to RI. In addition to freshwater systems with well-documented environmental histories like Lake Baikal, another freshwater ecosystem might also provide a unique opportunity to study the role of climate change in driving speciation in microeukaryotes and test hypotheses about the precise climatic events—and their molecular consequences—that cause morphological change and RI in this group of organisms.

The Greater Yellowstone Ecosystem (GYE) spans the states of Idaho, Montana and Wyoming in the continental United States. Several large freshwater lakes exist within the GYE: Yellowstone Lake, Lewis Lake, Heart Lake, and Shoshone Lake are all located within Yellowstone National Park, and Jackson Lake is located within Grand Teton National Park (Figure 5). All five of these lakes are characterized by high concentrations of silica and phosphorus and lower concentrations of nitrogen (Kilham et al. 1996; Theriot et al. 1997). However, the lakes differ in the timing and amount of nitrogen limitation, and periodically experience silica and minor phosphorus limitation during the summer months.

Yellowstone Lake is located 2.35 km (7,733 feet) above sea level, and is the largest high-elevation lake in North America. The lake has a surface area of 342 km² and formed after the collapse of the Yellowstone Caldera eruption approximately 630 thousand years ago (kyr) during the Late Cenozoic (Smith and Siegel 2000). The main lake body is located on the eastern margin of the former caldera and the southern part of the lake lies outside the caldera. Because of its high elevation and the cooler climate during the Pleistocene, the caldera was covered under a 1 km (~0.62 miles) thick ice cap at the top of the Yellowstone Plateau that spanned an area of more than 160 km (~99 miles) north to south, and approximately 113 km (~70 miles) east to west (Pierce et al. 2007). Several glacial cycles followed the caldera's formation, in which ice formed during cooling dry periods, and melted during warmer and wetter periods, and ended with the last glacial retreat (Pinedale Glaciation) roughly 14-16 kyr (Smith and Siegel 2000; Pierce et al. 2007). These repeated glacial cycles deepened Yellowstone Lake and nearby Jackson Lake, and also gave rise to many of the smaller surrounding lakes that dot the GYE. Glacial melt waters that ran through newly exposed sediments and bedrock supplied the lakes with large amounts of dissolved nutrients and potentially resulted in a continuous mixing of the lake waters. These conditions were ideal for the colonization by microeukaryotes as well as other groups of organisms that occupied Yellowstone Lake at the end of the Pleistocene.

Stephanodiscus niagarae and *S. yellowstonensis* are two closely related centric diatom species that reside in the lakes of the GYE (Kilham et al. 1996) and present an attractive model to study speciation in freshwater diatoms based on their morphological (Theriot and Stoermer 1984; Theriot 1992), genetic (Zechman et al. 1994; Theriot et al. 2006; Alverson 2007; Alverson et al. 2007), and ecological histories. *S. niagarae* is a widely distributed planktonic species that occupies a broad range of habitats from oligotrophic to eutrophic freshwater. The species is found in North America from the states of Alaska to California and from California

to Pennsylvania, and up to the Canadian Shield (Theriot 1992). The lineage appears to be at least two million years old (Theriot et al. 1988a), and fossils of this species are found as far as east as China and as far south as Guatemala (Theriot et al. 1988a; Theriot et al. 2006). *S. yellowstonensis* has been found only in Yellowstone Lake, where it co-occurs with 7 of the 12 common diatom species present in all lakes within the GYE (*Aulacoseira subarctica*, *Asterionella formosa*, *Cyclotella bodanica*, *Diatoma elongatum* var. *tenue*, *Rhizosolenia eriensis*, *Stephanodiscus minutulus*, and *Synedra* sp.1; Interlandi et al. 1999). *S. niagarae* and *S. yellowstonensis* are distinguished by striking differences in frustule morphology: *S. yellowstonensis* possesses fewer spines on the valve face and fewer pores compared to *S. niagarae*. Ancient lake sediments from Yellowstone Lake show fossilized cells that bear the modern *S. yellowstonensis* morphology occur throughout the last 9,800 years (Theriot et al. 2006). Prior to this period in which *S. yellowstonensis* appears to be the dominant species, various intermediate valve morphologies occur between a *S. yellowstonensis*-like and a *S. niagarae*-like morphology. The present-day species occupy allopatric distributions in the modern-day GYE: *S. niagarae* is found in most lakes of the GYE (Lewis, Heart and Jackson) except for Yellowstone Lake, whereas *S. yellowstonensis* is found only in Yellowstone Lake.

Figure 5. Map and hydrological profile of the Greater Yellowstone Ecosystem (GYE). The solid black line on the top map that extends from A to B corresponds to the vertical elevation shown on the bottom map. Lake depths and basin profiles were approximated using data from Theriot et al. (1997). The white dotted line on the top map marks the location of the Continental Divide. Y=Yellowstone Lake, S=Shoshone Lake, L=Lewis Lake, H=Heart Lake.

Paleontological History

The fossil record of the lake sediments dates back to around 14 kyr and shows that a *S. niagarae*-like ancestral species initially colonized the lakes of the GYE shortly after the glacial meltwaters filled the basin (Theriot et al. 2006). The fossil record also shows that its occupancy in Yellowstone Lake was short-lived (~13.7-12.2 kyr), and it was quickly replaced by *S. yellowstonensis*. The interval following colonization and before the disappearance of the *S. niagarae*-like ancestral species shows a transition between *S. niagarae* and *S. yellowstonensis* between 12.2-10.1 kyr, and shows a series of frustule morphologies characterized by a decreasing number of spines in the forms that precede modern *S. yellowstonensis* (Theriot et al. 2006). At 10.1 kyr, all cells in the record possess *S. yellowstonensis* valve morphology, coincident with a dramatically rapid increase in the size of the valve from a mean diameter of 40 μm to 64.3 μm . Valve diameter then steadily declines for the next 6,700 years until it returns to a mean of 41.3 μm around 3.4 kyr. Measurements of biogenic silica from the same core sediment (a rough indicator of diatom abundance) suggest a period of high productivity around 10.1 kyr. However, these data are difficult to interpret because strata of this age are marked not only by *S. yellowstonensis*, but also by *A. subarctica*, which possess more heavily silicified valves (Theriot et al. 2006).

The transition from *S. niagarae* to *S. yellowstonensis* thus occurs in a remarkably short period of approximately 1,500 years (Theriot et al. 2006). (It is worth mentioning that this also appears to be the one of the fastest examples of morphological character evolution in eukaryotes.) Theriot (1992) refers to this abrupt transition as a case of “time-transgressive morphological continuity” between fossils that appeared to be clearly *S. niagarae*-like and those that more closely resemble the extant *S. yellowstonensis*. Further studies show that *S. yellowstonensis* is not only morphologically divergent, but is also physiologically divergent: *S. yellowstonensis* can tolerate lower nitrogen levels than *S. niagarae* (Taylor 1994). Inorganic nitrogen is typically the growth-limiting nutrient in freshwaters, and diatom growth decreases substantially when nitrogen levels fall below the concentration of 10 μM (Interlandi et al. 1999). Diatoms in particular also become growth limited when silicon is low, because of the high silica requirement for frustule formation. *S. yellowstonensis* has a higher capacity for nitrogen utilization with an optimum intracellular ratio of silicon to nitrogen (Si:N) of 20:1, whereas *S. niagarae* maintains an optimum intracellular Si:N ratio of 2.5:1. *S. yellowstonensis* appears uniquely adapted to low nitrogen conditions; the species can survive and continue to grow under limited nitrogen conditions in culture, whereas low nitrogen conditions are lethal for *S. niagarae* (Kilham and Taylor 2002).

After the appearance of *S. yellowstonensis*, the core record shows the species was most abundant during two major historical droughts of the late 19th century and the Dust Bowl of the 1930's. Kilham et al. (1996) suggest that due to high light, low nitrogen to phosphorus ratio (N:P), and possibly low Si:P ratio caused by the decrease in precipitation, that these conditions may have shifted the competitive resource advantage to *S. yellowstonensis*, which appears to have experienced rapid population growth during these events. When conditions returned to wetter years with lower light, higher N:P ratio, and higher Si:P ratio due to external loading of nutrients, the coexisting diatom species *A. subarctica* began to dominate the plankton community as a presumed consequence of the shift in resource ratios. Although *A. subarctica* coexists with *S. yellowstonensis* in Yellowstone Lake, they are temporally isolated: *A. subarctica* blooms in early spring after ice-out when nutrients are high and light is low, whereas

S. yellowstonensis blooms in late summer when nutrients are lower and fewer diatom competitors are active (Kilham et al. 1996; Interlandi et al. 1999).

Events Leading to Speciation

The paleolimnological record of the lake suggests a sequence of climatic events that may have initiated the evolution of *S. yellowstonensis* and the subsequent morphological and physiological divergence between *S. niagarae* and *S. yellowstonensis*. The climate surrounding Yellowstone Lake during its formation was cool and wet, and the lake was either potentially continuously mixing or stratification was otherwise reduced— conditions that produced a turbid water column. The environmental change that occurred during the Younger Dryas Chronozone of North America had a dramatic impact on precipitation patterns of lake, which led to an alteration of the nutrient regime and changes in the mixing regime via thermal stratification of the epilimnion (upper most part of the water column). The Younger Dryas was a period of drying at the end of deglaciation from the Pleistocene, during which the climate shifted from cool and wet, to warm and dry. The rapid climate change altered the moisture balance of the region, and resulted in less runoff into the lake, which ultimately reduced the dissolved nutrient load (nitrogen, phosphorus, and silicon) being supplied from weathering bedrock. The Younger Dryas Chronozone spans ~12.9-11.7 kyr (Briles et al. 2012) and thus corresponds well with the timing of the rapid morphological changes observed between *S. niagarae* and *S. yellowstonensis* in the sediment transition zone.

Ecological studies of the modern Yellowstone Lake show that water chemistry is tightly linked to climatic conditions (Kilham et al. 1996). Increased cloud cover (decreasing light levels for photosynthesis) and increased precipitation (increasing nutrient influx to the lake) alter the abundance of the dominant phytoplankton in the lake. The consequences of these events are changes in lake dynamics toward different species composition with different optimal growth conditions (Kilham et al. 1996; Interlandi et al. 2003). The *S. niagarae*-like ancestor of *S. yellowstonensis* colonized the lake during a period when the lake was surrounded by sage and grass vegetation (13.7-12.0 kyr). Around 12.0 kyr the vegetation changed to a Lodgepole pine forest dominated by *Pinus contortus*, *Pinus albicaulis*, *Artemisia*, *Abies*, *Juniperus*, and *Picea* species, which marked expansion of the closed forest and shrinking of meadows that surrounded the lake. Warmer, drier summers also contributed to increased summer insolation of the lake and earlier ice-off of the lake following winter, which occurred 11.0-6.0 kyr. During warmer periods characterized by temperatures above 15 °C, Yellowstone Lake also becomes thermally unstable, which causes the thermocline (the water layer between the warm upper water column and cold lower water column) to move, whereas Lewis Lake and Jackson Lake, which *S. niagarae* inhabits, have more stable summer thermoclines (Interlandi et al. 1999). The most important consequence of these changes, was the decrease in nitrogen availability in the lake. It is during this period that the morphological transition between the two *Stephanodiscus* species is first observed in the sediments of Yellowstone Lake.

This raises the question of a possible connection between adaptation to a lower nitrogen environment and the change in valve morphology experienced by *S. yellowstonensis*. Transitional forms in the lake core records show what appear to be several clonal lineages altering their valve morphologies as lake stability and nitrogen concentrations decreased. Interestingly, differences in nitrogen abundance causes a change in valve morphology in a sister

species to *S. niagarae* and *S. yellowstonensis*, *S. alpinus* (Theriot et al. 1988b). Specifically, differences in the N:P ratio alters the valve costae:spine ratio in *S. alpinus*— high N:P ratio gives rise to lower costae:spine ratio and low N:P ratio gives rise to higher costae:spine ratio. Thus, as nitrogen level in Yellowstone Lake began to decrease, it seems possible that a coincident change in valve morphology may have given rise to morphological changes observed in *S. yellowstonensis*. Because *S. yellowstonensis* can survive nitrogen rich water, the possibility exists to directly test the consequence of this morphological change on RI. In particular, future research might test the hypothesis that morphological evolution drove the evolution of RI, by adjusting nitrogen levels to alter the valve morphology in *S. yellowstonensis* and measure its effect on RI between *S. yellowstonensis* and *S. niagarae*. The *S. niagarae*-*S. yellowstonensis* species pair is also a prime opportunity to bring new molecular technologies to bear on dissecting the genetic and molecular bases of RI in freshwater diatoms. Sequence data from whole genomes and whole transcriptomes of both species from all of the lakes in the GYE would facilitate identifying regions of the genome under selection, and narrow down potential candidate genes that contribute to morphological differences and RI between these two species.

CONCLUSION

Although the mechanisms of speciation in diatoms have received little attention over the past two centuries, recent work has initiated the requisite momentum to begin to thoroughly investigate processes of speciation in this large group of eukaryotes. Importantly, understanding the nature of environmental changes experienced by diatom communities is likely to prove crucial to identifying general mechanisms by which speciation occurs in diatoms.

One potentially informative avenue for future research efforts will be understanding the nature and the frequency of environmental stresses on the evolution of different types of prezygotic isolation between species. Although isolating mechanisms other than those discussed above are also likely to be at work in diatoms, detailed studies of their potential importance in diatom speciation have not yet been performed. Two barriers to gene flow in particular will likely provide fruitful avenues of future research. Diatoms occupy every global aquatic niche, which suggests that ecological isolation may play a predominant role in diatom speciation. Even among co-occurring taxa that reside within a single freshwater pond, adaptation to different niches presents the possibility of microallopatry among populations that occupy the epilimnion (top layer of benthic mud), epilithic (rocks), epiphyton (plant vegetation), and epizoic (animals) zones within the same body of water. Another mechanism of RI that could prove important is gametic isolation, particularly among those diatom species that produce motile gametes.

Perhaps most interesting is the general role that differences in cell morphology might play in the evolution of RI. Among some groups of diatoms, there is growing evidence that cell morphology appears to be important for successful sexual reproduction. If changes in frustule morphology are a common response to changes in the environment, understanding how the environment directs the evolution of morphology might provide great insight into mechanisms of speciation in the microeukaryota.

ACKNOWLEDGMENTS

We are grateful the editor for the invitation to contribute this chapter to the book. We thank D. Mann, T. Rynearson, and E. Theriot for helpful comments on the manuscript. This work was supported by funds from the University of Oklahoma.

ABSTRACT

The evolution of new species without geographic isolation has received a great deal of attention over the past decade. The mechanisms that can lead to speciation of vascular plants in biogeographic sympatry fall broadly into three categories; speciation with ongoing gene flow (which is often, but not always, synonymous with ecological speciation), hybrid speciation and polyploid speciation. Here, with a particular focus on plant species, we briefly review the concepts and research on sympatric speciation and its causes. Hybrid speciation and polyploid speciation have occasionally been dismissed as special (“simple”) cases of sympatric speciation and we consider that, although they are distinctive, there are significant obstacles to overcome before new species can be generated by these mechanisms. As such they are deserving of as much research attention as is currently afforded to speciation with gene flow. We argue that it remains important to continue identifying cases of speciation in sympatry, in order to gain a better understanding of how all of these mechanisms can drive speciation in restricted areas (rather than simply to quantify sympatric speciation per se) and we elaborate on the usefulness of Lord Howe Island as a model system for speciation research with this in mind.

INTRODUCTION

Allopatric and Peripatric Speciation

Species divergence in geographic isolation (allopatry) continues to be widely accepted as the most common geographic mode by which speciation can occur (Coyne and Orr 2004; Mayr 1963; Mayr 1982). Peripatric speciation is a special case of allopatric speciation where one of the initial populations is very small (Mayr 1982). Ongoing gene exchange is considered to be a major hindrance to population splitting and, ultimately, to the evolution of new species (Coyne 1992; Mayr 1963). Complete geographic isolation of populations prevents gene flow between them, allowing the processes of genetic drift and mutation to cause genetic divergence and, given enough time, to the evolution of genetic incompatibilities causing intrinsic prezygotic or postzygotic reproductive isolation of the groups (Coyne and Orr 2004). Under this scenario, divergent or sexual selection are not actually necessary for new species to evolve, although they are likely to play important roles in extrinsic prezygotic and postzygotic reproductive isolation and reinforcement if species' ranges shift and they come into secondary contact (Coyne and Orr 2004; Schluter and Conte 2009; Sobel, et al. 2009).

Sympatric and Parapatric Speciation

“But from reasons already assigned I can by no means agree with this naturalist [Moritz Wagner], that migration and isolation are necessary elements for the formation of new species.”
- Charles Darwin (1859; p79, sixth edition).

Sympatric and parapatric speciation differ from the other modes in that geographic isolation of diverging populations is not complete and speciation occurs despite some genetic exchange (Coyne and Orr 2004; Fitzpatrick, et al. 2008; Mallet, et al. 2009). In order for species to diverge without geographic isolation, a biological mechanism is required to counter-balance the homogenising effect of gene flow (Coyne 1992; Dieckmann and Doebeli 1999; Tregenza and Butlin 1999). Definitions of sympatric and parapatric speciation come in two forms. Biogeographic definitions focus on the spatial geographic pattern under which speciation is initiated. Alternatively, population genetic definitions, are concerned with the probabilities of mating and migration between populations during divergence (for examples of each see Fitzpatrick, et al. 2008). The relative merits and disadvantages of both views continue to be debated thoroughly (Bird, et al. 2012; Butlin, et al. 2008; Coyne and Orr 2004; Fitzpatrick, et al. 2009, 2008; Gavrillets 2003; Kisel and Barraclough 2010; Mallet, et al. 2009).

In population genetic definitions allopatric and sympatric speciation form two extreme ends of a scale. At one end of the scale, two species evolve from completely isolated populations (allopatric speciation), at the other, two species arise from a single panmictic population (sympatric speciation). Speciation events that take place under the varying levels of migration and mating that exist between these extremes constitute parapatric speciation (Butlin, et al. 2008; Fitzpatrick, et al. 2009; Gavrillets 2004; Gavrillets 2003; Mallet, et al. 2009). Population genetic definitions are sufficiently precise to be applied in mathematical models of speciation and have been applied in this context to demonstrate that speciation under these conditions is theoretically possible (Gavrillets and Vose 2007; Gavrillets, et al. 2007; Tregenza

and Butlin 1999), but they contain no explicit spatial component (Fitzpatrick, et al. 2009, 2008; Mallet, et al. 2009). This has lead some researchers to hypothesise that parapatric speciation is the dominant force in nature as the criteria for allopatric and sympatric speciation are so specific that they must be by definition rare (Butlin, et al. 2008; Fitzpatrick, et al. 2008; Mallet, et al. 2009; Nosil 2008). Additionally, the requirement of initial panmixia for sympatric speciation is nearly impossible to translate to the study of wild populations, as we cannot directly observe the event and mating in wild organisms may never truly be random (Butlin, et al. 2008; Endler 1977; Mallet, et al. 2009).

As others have noted, this slightly trivialises the debate over the role of geographic isolation in the speciation process (Mallet, et al. 2009). Despite the criticism that biogeographic definitions contain artificially discrete categories (Butlin, et al. 2008; Mayr 1982), they allow us to address Mayr's proposition that allopatric speciation has been the dominant mode, as well as limiting the evolutionary forces that might be acting in different situations (Coyne and Orr 2004; Mallet, et al. 2009). Consequently, empirical studies addressing the geography of speciation (Barracough and Vogler 2000; Coyne and Price 2000; Fitzpatrick and Turelli 2006; Kisel and Barracough 2010; Krug 2011; Papadopoulos, et al. 2011; Phillimore, et al. 2008; Stuessy, et al. 2006) or investigating specific speciation events (Babik, et al. 2009; Barluenga, et al. 2006; Bird, et al. 2011; Crow, et al. 2010; Savolainen, et al. 2006a) commonly adopt biogeographic definitions. In some cases this is not explicitly stated, instead authors refer to divergence in allopatry or sympatry, e.g., Quesada *et al.* (2007). For the remainder of this chapter the broadest, biogeographic definition of sympatric speciation (see Bird, et al. 2012) is used unless otherwise stated.

Empirical Studies of Speciation

Studying natural populations offers a way to bridge gaps in our scientific knowledge that it is currently not possible to address in laboratories or with mathematical modelling. In speciation research, studies of wild populations generally take advantage of four approaches, either singly or in unison. (i) Isolated islands and archipelagos are particularly useful for speciation research as they often harbour high proportions of endemic species and can be considered as relatively closed systems (Coyne and Price 2000; Kisel and Barracough 2010; Losos and Schluter 2000; Savolainen, et al. 2006a; Stuessy, et al. 2006). (ii) In some groups of organisms, parallel evolution of morphotypes/ecotypes from separate origins allows direct comparison of the processes acting in independent replicates. Despite being relatively rare occurrences, several of these natural experiments have proved to be incredibly fruitful sources of research (e.g., Butlin, et al. 2008; Losos and Miles 1994; McKinnon, et al. 2004; Nosil, et al. 2008; Peccoud, et al. 2009; Rundle, et al. 2000). (iii) Identification of recently diverged sister species or ecologically and phenotypically divergent populations of the same species have provided evidence for the ecological drivers and genetic basis of divergent/disruptive selection and reproductive isolation (Bonin, et al. 2006; Chamberlain, et al. 2009; Hoekstra, et al. 2006; Jiggins, et al. 2001; Ramsey, et al. 2003; Szymura and Barton 1991). (iv) Phylogenetic comparative methods (Felsenstein 1985) have been used to investigate the geographic mode of speciation (Barracough and Vogler 2000; Fitzpatrick and Turelli 2006; Losos and Glor 2003), ecologically driven trait evolution (Losos 1994) and increased rates of species divergence (Barracough, et al. 1999; Barracough and Nee 2001; Barracough, et al. 1998a; Barracough,

et al. 1998b), and adaptive radiations (Baldwin 1997; Schluter 2000). In terms of studying sympatric speciation these approaches can, and have, been applied to macroevolutionary studies addressing the geographic setting of speciation and microevolutionary studies concerned with both identifying case studies and investigating the mechanisms and barriers driving divergence.

Approaches Studying Sympatric Speciation

It is well established that geography plays a key role in the formation of new species (Mayr 1963), however, there is still controversy as to whether geographic separation is actually necessary for speciation to occur and as a result, it is unclear to what extent each of the geographic modes of speciation (allopatric, sympatric, parapatric and peripatric) have contributed to current diversity patterns (Barracough and Nee 2001; Barracough and Vogler 2000; Coyne and Orr 2004). A major obstacle is that as time accumulates following a speciation event, so too can adaptive changes allowing sister species to co-exist. As a consequence post-speciation range shifts can mask the original geographic setting for speciation events (Berlocher 1998). This confounds attempts to unravel geography's influence on speciation events in both macro-evolutionary (Barracough and Nee 2001; Barracough and Vogler 2000; Fitzpatrick and Turelli 2006) and micro-evolutionary studies (Crow, et al. 2010; Rundle, et al. 2000; Schliewen, et al. 1994). Two main approaches have been applied to studies assessing the frequency of speciation modes: (i) comparative studies using current species distributions to infer the geographic distribution at speciation events, making the assumption that current distributions reflect ancestral distributions (Barracough and Vogler 2000; Fitzpatrick and Turelli 2006; Krug 2011; Losos and Schluter 2000; Phillimore, et al. 2008) and (ii) assessments of the frequency of co-occurring endemic island species belonging to the same genus, under the assumption that these cases constitute *in situ* speciation events (Coyne and Price 2000; Kisel and Barracough 2010; Stuessy, et al. 2006).

Overall, very few studies have attempted to address the frequency of speciation without geographic isolation within whole communities or taxonomic groups, and most that have indicate that it is exceptionally rare (Barracough and Vogler 2000; Coyne and Price 2000; Fitzpatrick and Turelli 2006; Losos and Schluter 2000; Phillimore, et al. 2008). Kisel and Barracough (2010) demonstrated that the geographic scale required for speciation is related to the spatial scale of gene flow, and so, for organisms to speciate on small islands they must have very restricted dispersal. In animals, speciation at small spatial scales has been ruled out for some taxa, e.g., in island birds (Coyne and Price 2000) and Caribbean *Anolis* lizards (Losos and Schluter 2000), but may be more common in others, e.g., marine gastropods (Krug 2011). Until recently, evidence from comparative studies that sympatric speciation is uncommon appeared to be borne out by the scarcity of convincing case studies found in nature. However, this may have been a reflection of the difficulties faced when attempting to prove that sympatric speciation has taken place, rather than due to its limited occurrence (Berlocher 1998; Coyne and Orr 2004). For reasons mentioned above, current sympatry of species is insufficient to be confident of the geographic setting during speciation. Coyne and Orr (2004) proposed four conditions that need to be fulfilled for confirmation of a sympatric speciation event; (1) species must be sister taxa, (2) species must occur in sympatry, (3) species must demonstrate reproductive isolation and (4) an allopatric phase in their divergence must be highly unlikely.

Figure 1. Map showing the location of Lord Howe Island in the Tasman Sea and surrounding landmasses.

To evaluate these criteria studies have typically used: phylogenetic evidence of species relationships to address the first criterion; surveys of species distributions to assess the second; crosses, reciprocal transplants and population genetic approaches to determine the extent of reproductive isolation and; focusing on species pairs from recently formed, and isolated lakes and islands to confirm the fourth. Few studies have managed to conclusively demonstrate all four conditions, often struggling to successfully confirm the last - which is considered the strictest and most critical. Studies of cichlids in crater lakes (Barluenga, et al. 2006; Elmer, et al. 2009), palms on an oceanic island (Babik, et al. 2009; Savolainen, et al. 2006a) and host switching in African indigo birds (Sorenson, et al. 2003) constitute some of the most convincing cases of biogeographic sympatric speciation described, however, even these are not without their detractors (Bolnick and Fitzpatrick 2007; Stuessy 2006a). The discovery of these cases and mathematical modelling of sympatric speciation (Dieckmann and Doebeli 1999; Gavrillets 2003; Gavrillets and Vose 2007; Gavrillets, et al. 2007; Tregenza and Butlin 1999) has led some researchers, particularly those investigating speciation in aquatic environments, to suggest that

this criterion is too strict and limits our ability to effectively study an interesting phenomenon (Bird, et al. 2012; Bird, et al. 2011; Crow, et al. 2010; Krug 2011). In the case of broadcast-spawning Hawaiian limpets (Bird, et al. 2011) this is certainly a justified viewpoint, however, it is currently unclear whether this view will garner widespread support (Elmer and Meyer 2010), particularly, as confirmed cases of sympatric speciation seem to be sporadic and at low frequency. Recent work investigating sympatric speciation on Lord Howe Island (LHI; Figures 1 and 2) may tip the balance in this argument. Papadopoulos et al. (2011) built upon earlier research into palm trees and used Coyne and Orr's criteria to confirm whether or not congeneric species of plants on the island had speciated in sympatry - providing the first assessment of the frequency of confirmed sympatric speciation events at a specific location. By examining the phylogenetic relatedness of multiple species pairs/groups, this research demonstrated that at least 4.5% of species and perhaps as much as 8.2% of the extant species on LHI were the products of sympatric speciation events.

Figure 2. (a) Reconstruction of LHI and Ball's pyramid past and present developed from bathymetric readings (Kennedy 2002). White areas surrounded by black outline denote the current extent of LHI and Ball's pyramid. Shaded areas, depict the largest area of the islands in the past, are currently between 0-100m below sea level. Darker shades indicate increased depth. The historical maximum distance from one point on LHI to another on Ball's Pyramid has been shown to be too small for allopatric speciation to occur (Papadopoulos, et al. 2011) (b) Shaded relief map of LHI.

Causes of Reproductive Isolation during Sympatric and Parapatric Speciation

In sexual organisms, speciation in sympatry/parapatry can occur via speciation-with-gene-flow, homoploid hybrid speciation (sometimes known as recombinational speciation) and allo- and auto-polyploid speciation. In each case there are several mechanisms that can potentially initiate divergence and lead to speciation but these classes can be distinguished in two ways. First, in both forms of polyploid speciation, reproductive isolation of the emergent species is a nearly instantaneous by-product of polyploidisation (Coyne and Orr 2004; Mallet 2007;

Ramsey and Schemske 1998; Rieseberg and Willis 2007). On the other hand, the evolution of reproductive isolation in homoploid hybrid speciation and speciation-with-gene-flow may or may not be reliant on some form of divergent selection and is unlikely to occur in a single step (Coyne and Orr 2004; Dieckmann and Doebeli 1999; Gompert, et al. 2006; Mallet 2008; Nosil, et al. 2009; Rundle and Nosil 2005; Tregenza and Butlin 1999). It is important to note that divergent selection is almost certainly instrumental in the persistence of the species generated by all of the above processes, but does not play a role in the evolution of reproductive isolation during polyploidisation (Coyne and Orr 2004; Rundle and Nosil 2005; Schluter 2001, 2000; Sobel, et al. 2009). The second difference relates to the number of species required to initiate a new speciation event. When autopolyploidisation and speciation-with-gene-flow occur, two distinct species arise from a single ancestral population. Allopolyploid and homoploid hybrid speciation both require the crossing of two distinct species to generate a third lineage (Coyne and Orr 2004; Gavrillets 2004; Mallet 2007; Ramsey and Schemske 1998; Rieseberg and Willis 2007).

We collated data from a variety of sources to evaluate the extent to which these processes have been studied in island systems (Table 1). Using the island angiosperm data collected by Kisel and Barraclough (2010) and Steussy et al. (2006) as a starting point, we reviewed angiosperm species lists for islands without data in the previous studies. We then expanded on the phylogenetic data examined by Kisel and Barraclough (2010) by performing a systematic search to find evidence of within island sister species. This was carried out using the web of science with search terms “phylogenetic” and the name of each genus or the name of the island (for regions larger than 5000km²). We recorded the number of species whose relationships had been examined using molecular phylogenetic approaches and the number of species with a sister species within the same island/archipelago recovered unequivocally in these phylogenetic reconstructions. We then searched for population genetic research into homoploid hybrid speciation on these islands using the island name and “homoploid hybrid” and “diploid hybrid” as search terms. Finally, using the Index to Plant Chromosome numbers database (IPCN, <http://www.tropicos.org/Project/IPCN/>) we recorded the number of island genera for which ploidy assessments have been carried out and the number of these studies which found evidence for chromosome number variation within genera on a single island. All data is presented in Table 1.

Speciation-with-Gene-Flow

One of the central questions in speciation research is how ecologically driven divergent or disruptive selection might lead to population differentiation, reproductive isolation and the eventual evolution of new species in the face of ongoing gene flow (Butlin, et al. 2008; Hendry, et al. 2007; Kirkpatrick and Ravigné 2002; Mallet 2008; McKinnon, et al. 2004; Rundle and Nosil 2005; Schluter 2001). Divergent or disruptive selection pressures imposed by ecological interactions can have a considerable impact on divergence of adaptive morphological and physiological traits. For this to develop into “ecological speciation” this environmentally driven divergence needs also to be the root mechanism by which barriers to gene flow evolve between populations (Coyne and Orr 2004; Rundle and Nosil 2005; Schluter 2001). The term ecological speciation has been accused of being a misnomer as ecology is expected to play some role in

all speciation events (Sobel, et al. 2009), however, we use it here as the concept is clearly defined and widely applied (Nosil 2012).

Three components are required to cause ecological speciation with gene flow; an ecological source of divergent selection, a reproductive isolating mechanism and a genetic mechanism to link the divergent selection and isolation (Kirkpatrick and Ravigné 2002; McKinnon, et al. 2004; Rundle and Nosil 2005; Schluter 2001, 2000). Ecological divergent selection can stem from numerous sources that are not mutually exclusive. Factors promoting divergent selection may be abiotic - such as climate, habitat structure and resource abundance - or biotic - such as sexual selection, inter- or intra-specific competition and predation (Rundle and Nosil 2005; Schluter 2000). Similarly, reproductive barriers can take various forms, both prezygotic (e.g., habitat isolation, temporal isolation, pollinator isolation, behavioural isolation) or postzygotic (e.g., Hybrid inviability or sexual selection against hybrids; Coyne and Orr 2004; Rundle and Nosil 2005; Schluter 2000; Sobel, et al. 2009). In order for divergent selection and reproductive barriers to interact and lead to population divergence a genetic mechanism is required to link the two processes, making them heritable. Theoretically, this can occur via the evolution of a pleiotropic ‘magic trait’, through linkage disequilibrium between genes involved in local adaptation and assortative mating, or because ecological differences within a species range produce divergent genetic adaptations as well as plastic responses that confer reproductive isolation (e.g., environmentally controlled shifts in flowering time; Coyne and Orr 2004; Devaux and Lande 2008; Dieckmann and Doebeli 1999; Gavrillets 2003; Mallet, et al. 2009; Tregenza and Butlin 1999). Uniform selection (mutation order speciation) and genetic drift may play important roles during ecological speciation in allopatry, but not in sympatry or parapatry (Coyne and Orr 2004; Schluter 2009). Evidently, the genetic basis of divergence and the nature of the isolating barriers may differ between specific speciation events, nevertheless, divergent natural selection is likely to be the driving force behind the evolution of reproductive isolation in many instances of speciation-with-gene-flow (Dieckmann and Doebeli 1999; Doebeli and Dieckmann 2003; Doebeli, et al. 2005; Higashi, et al. 1999; Kirkpatrick and Ravigné 2002), although other mechanisms may lead to speciation in some instances (e.g., through sexual selection as Fisherian runaway; van Doorn, et al. 1998).

Determining whether sympatric speciation with gene flow has occurred requires, not only, that Coyne and Orr’s criteria are fulfilled but, additionally, the sister species relationship recovered in phylogenetic reconstructions must not be an artefact of hybridization. Although it is not stated explicitly in the criteria, hybrid speciation (homoploid or polyploid) would be excluded by criterion one if both progenitors have been sampled in a phylogenetic study, as long as the resolution of the gene regions used is sufficient. Furthermore, if polyploidisation (assessed using chromosome counts or genome size estimation) is not evident in the sympatrically diverging species then fulfilment of these criteria is a strong indication that speciation in the face of strong gene flow has taken place (Coyne 2011; Papadopoulos, et al. 2011).

In plants, cases of ecological divergence despite ongoing gene flow, a precursor to speciation, have been proposed using statistical inference of historical gene flow for genetic markers (e.g., in *Oryza* and *Pinus*; Wachowiak, et al. 2011; Zheng and Ge 2010). However, examples of sympatric speciation with gene flow are limited to those found in *Howea*, *Metrosideros* and the radiation of *Coprosma* on Lord Howe Island (LHI), where polyploidisation, hybrid speciation and divergence in allopatry could be ruled out with a reasonable degree of confidence (Coyne 2011; Papadopoulos, et al. 2011; Savolainen, et al.

2006a). Despite this lack of proven cases there are many other potential instances of divergence with gene flow in island plants. Estimates of cladogenetic divergence within islands and archipelagos, based on the presence of congeners, reveal surprisingly large numbers of co-occurring species pairs (Table 1; Kisel and Barraclough 2010; Stuessy, et al. 2006). It is important to point out that more detailed analyses have shown in the case of LHI (Papadopoulos, et al. 2011), and the general patterns observed in the data collated here, that these are over-estimates of *in situ* cladogenesis, but the existing phylogenetic evidence shows that there are sister species present on many islands. However, even when sister species are present on an island, polyploidisation, hybrid speciation and geographic isolation are also good candidates for drivers of divergence, particularly in the case of archipelagos and the larger islands (Coyne 2011; Kisel and Barraclough 2010; Papadopoulos, et al. 2011). Alternatively the patterns observed may be driven by extinctions or multiple colonisations. Further identification and investigation of sympatric speciation events in island plants has the potential to greatly advance our understanding of the mechanisms allowing the evolution of reproductive barriers in the face of ongoing genetic exchange and the contribution this kind of speciation has made to patterns of global biodiversity (Coyne 2011).

Homoploid Hybrid Speciation

The process by which new genotypes are generated differs between homoploid hybrid speciation and speciation with gene flow. Despite this, the same obstacle of continuing gene exchange must be overcome in order for hybridisation to progress to speciation. Without allopatric separation of the hybrid population this is believed to occur through ecological speciation in a similar fashion to speciation with gene flow (Buerkle, et al. 2000; Gross and Rieseberg 2005; Mallet 2007; Mavarez, et al. 2006; Rieseberg and Willis 2007). An additional problem also faces new hybrid species; competition with its progenitors. Hybrid genotypes are unlikely to be at a competitive advantage in either of the parent species habitats, for them to persist they must be pre-adapted to, and near the fitness maxima of, an available niche (Coyne and Orr 2004; Mallet 2007; Rieseberg and Willis 2007; Sobel, et al. 2009). This insight has led to the general acceptance that homoploid hybrid speciation is relatively rare, but a number of examples exist in both plants (Rieseberg, et al. 2003; Rieseberg, et al. 1995) and animals (Gompert, et al. 2006; Mavarez, et al. 2006). Alternatively, hybrid genotypes may benefit from improved utilisation of one of the parent species niches leading to its extinction, making the detection of hybrid speciation more problematic (Gross and Rieseberg 2005; Mavárez and Linares 2008).

The genetics and ecology of hybrid speciation is a vibrant area of research, providing insight into adaptive radiations and the role of divergent selection in reproductive isolation. By definition homoploid hybrid speciation occurs in sympatry and, despite plentiful evidence of reticulate evolution and hybridisation in island plants gleaned from phylogenetic studies (e.g., Howarth and Baum 2005; Liu, et al. 2009), it is expected to be rare in very restricted areas where co-occurrence of reproductively compatible species is less likely and the opportunity for a newly formed hybrid lineage to escape competition with its progenitors is significantly diminished. Phylogenetic work on LHI suggests that at least two plant species (*Calystegia affinis* and *Myrsine mcomishii*) are likely to be of hybrid origin, although in both cases it is not clear whether hybridisation did in fact take place on the island (Papadopoulos, et al. 2011).

Although it is expected to be uncommon, surprisingly little research has evaluated whether potential cases can truly be considered as homoploid hybrid speciation (rather than examples of introgressive hybridisation) using population genetic methods (e.g., Brochmann, et al. 2000; Friar, et al. 2006; Remington and Robichaux 2007; Smith, et al. 1996). Our recent population genetic research into the origins of the LHI *Coprosma* species suggests that two species may be the result of hybridisation between species that had previously diverged via speciation with gene flow on the island (Papadopoulos, et al. 2012). The few well studied instances show that homoploid hybrid speciation can occur on islands, but the frequency and mechanisms that govern this process remain heavily understudied.

Polyplloid Speciation

Polyplloid individuals possess three or more complete assemblages of chromosomes. When a new species arises as a result of an increase in the number of chromosome sets this is known as polyplloid speciation (Mallet 2007; Ramsey and Schemske 1998; Rieseberg and Willis 2007). In these cases speciation is expected to be virtually instantaneous because of the incompatibility and sterility associated with crosses between the original species and the polyplloid species (Ramsey and Schemske 1998). Polyplloidisation can develop through three main mechanisms; somatic doubling, meiotic non-reduction and polyspermy (Mallet 2007; Ramsey and Schemske 1998; Rieseberg and Willis 2007). New polyplloid species can either be derived from a single progenitor (autopolyploidy) or by hybridisation of two distinct species (allopolyploidy; Ramsey and Schemske 1998). Estimates of the frequency of polyplloid speciation in nature vary according to the method used and the group assessed (Coyne and Orr 2004). In animals, polyplloid speciation is generally accepted to be exceptionally rare (Otto and Whitton 2000), whereas in vascular plants recent estimates range from 2 - 15% in angiosperms and 7 - 31% in ferns (Otto and Whitton 2000; Wood, et al. 2009). Why is there such a difference in rates of polyplloidisation between plants and animals? There is no conclusive answer to this question, several hypotheses have been proposed and subsequently dismissed (Mable 2004; Orr 1990). Probably the most popular view is that the presence of genetically degenerate sex chromosomes (relatively uncommon in plants) results in incompatibilities in tetraploids, but this too does not satisfactorily explain the variation in rates of polyplloidy between the different groups (Orr 1990).

Allopolyploid speciation is often considered to occur considerably more frequently than autopolyploid speciation, despite the fact that autopolyploidisation has been estimated to occur at higher rates than allopolyploidisation (Coyne and Orr 2004; Mallet 2007; Ramsey and Schemske 1998). The discrepancy between the rates of auto- and allopolyploidy and the frequency of subsequent speciation may be for two reasons: (1) although autopolyploids form more often, they may be less capable of persisting as they are usually ecologically similar to, and thus in competition with, their progenitors. The result is that they frequently go extinct or replace the original diploid species. As with other hybrids, allopolyploids are often morphologically and ecologically divergent from the progenitor species and so may be better suited to co-exist or colonise new habitats (Mallet 2007; Ramsey and Schemske 1998; Rieseberg and Willis 2007; Sobel, et al. 2009). (2) Autopolyploids are often morphologically indistinguishable from their diploid progenitors and as a result they may not be detected. This problem is further compounded by the reticence of taxonomists to describe cryptic polyploids

as new species (Rieseberg and Willis 2007; Soltis, et al. 2007). Although opinions differ over which explanation is more likely, it is generally accepted that allopolyploid speciation is much more common (Mallet 2007).

For similar reasons to homoploid hybrid speciation, allopolyploid speciation and autopolyploid speciation are expected to be rare in island systems; indeed very few of the genera tested to date have shown any chromosome number variation (Table 1). In addition, no angiosperm genera with confirmed sister species present, with the exception of those on the larger island and archipelagos, show signs of polyploidisation; however, very few have actually been tested. The competitive difficulties that face a new polyploid lineage are very similar to those faced by a homoploid hybrid, however, polyploidisation is often considered to cause instant reproductive isolation and, unlike the other mechanisms, one of the major barriers to speciation (i.e., gene flow) is circumvented. Recently, research has shown that not only has gene flow occurred from diploids to tetraploids in natural populations (a widely acknowledged phenomenon; Soltis and Soltis 1999) but is bidirectional in some groups (e.g., *Arabidopsis* and *Dactylorhiza*; Jørgensen, et al. 2011; Ståhlberg 2009). Studying polyploidisation in island plants offers an opportunity to understand how new lineages escape competition with their progenitor/s and whether gene flow between ploidal levels has implications for the ease of sympatric speciation via polyploidisation.

LORD HOWE ISLAND: A MODEL SYSTEM FOR STUDYING SPECIATION

Lord Howe Island Formation and Climate

Lord Howe Island (LHI) is a small island (16 km²; Figures 1 and 2) lying at the southern end of a 1000 km line of volcanic seamounts which extends northwards along the Lord Howe Rise (McDougall, et al. 1981; Pickard 1983). Located 600 km east of Australia (Figure 1), the nearest seamount, Ball's Pyramid, emerges from the sea some 24 km SSE of LHI (Figure 2a). The next link in the chain is Elizabeth reef approximately 170 km north. The island is the eroded remains of a large shield volcano which first became active 6.9 mya and rapidly became dormant, producing the last of the island's basaltic rocks 6.4 mya (McDougall, et al. 1981). The island sits on a shelf that is 24 km wide and 36 km from north to south and is surrounded by a fringing reef that forms a large lagoon on the western side (Woodroffe, et al. 2006). Currently, the landscape is highly heterogeneous, in the south two heavily eroded mountains, Mt. Lidgbird (777 m) and Mt. Gower (875 m), dominate the skyline with numerous cliffs and creeks intersecting the area to produce a patchwork of different habitats (McDougall, et al. 1981; Pickard 1983).

Studies of the geology and bathymetry indicate that the volcanic areas of LHI currently above sea level were rapidly eroded into their current state within 1-2 Myr of the initial eruption and have since been buffered from significant wave erosion by the presence of coral reefs (Brooke 2003; Kennedy 2002; Woodroffe, et al. 2006). LHI and Ball's pyramid lie on either side of the southerly limit to fringing reef formation, known as the Darwin point. The younger Ball's Pyramid possess no reef to provide protection from erosion and has undergone significant (almost complete) planation, whereas LHI has migrated northwards into reef building seas and is protected by a fringing reef (Woodroffe, et al. 2006). These studies also

indicate that neither LHI nor Ball's pyramid have subsided, but changes in sea level during glacial periods would have increased the size of both to the extent of the shelves upon which they sit (Brooke 2003; Kennedy 2002; Woodroffe, et al. 2006). Despite the increased size of the island during brief periods in its history, population genetic analyses for a range of plant species suggest that at no point would geographic distance between individuals of a species have been sufficient to allow neutral differentiation, particularly for wind dispersed plants (Papadopoulos, et al. 2011). In other words allopatric divergence is very unlikely to have played a role during speciation on LHI.

Deposition of calcareous material during periods of low sea level in the late Pliocene and Pleistocene provided the island with the sedimentary Ned's Beach Calcarene which is dominant in the north of the island below 100 m (McDougall *et al.* 1981). The volcanic edifice of Elizabeth reef formed 10.2 mya and rises abruptly from 2000 m below sea level. The Elizabeth reef pedestal is considerably smaller than that of LHI and Ball's Pyramid (10.7 km by 6.2 km) and is capped by an atoll that extends to a depth of 40 m (McDougall, et al. 1981; Woodroffe, et al. 2004). Currently, no plant life is found at Elizabeth reef and only five, highly salt tolerant, plant species occur on Ball's Pyramid, all of which can also be found on LHI (Green 1994; Priddel, et al. 2003). The tropical location, small size and considerable erosion of the Elizabeth reef sea mount suggest that it is unlikely to have been a large and ecologically similar island during the life time of LHI.

LHI's climate is essentially sub-tropical with the humidity ranging between 68 and 73 percent throughout the year (Pickard 1983). The mean number of rain days per month ranges from 11 in summer to 22 in the winter with a similar seasonal pattern seen in the mean monthly precipitation (Gentili 1971; Pickard 1983). Cloud cover is often present, particularly around the mountains which generate their own orographic cloud. As a result rainfall in the south is more common, producing a wetter environment. Mean annual temperature is 19.1°C and temperatures at the summits are calculated to be about 6-8°C lower than the lowlands. There is no record of a frost ever hitting the island. Wind speeds and directions do vary dramatically, but onshore resultants for winds from the North-east and South-east are considerably more dominant and stronger in magnitude (Pickard 1983). These variations in climate generate localised microclimatic changes enhancing the patchiness of the environment.

The Vegetation of LHI and the Impact of Human Settlement

Habitat differentiation on the island is reflected in the vegetative assessment of Pickard (1983), in which he identified nine broad scale vegetative formations which were then divided into 18 plant alliances, these in turn he further classified into finer scale plant associations. Although highly detailed and thoroughly documented, these associations and the map of their distributions do not completely capture the variation that is actually present on the island. The composition of the communities found within these associations can vary dramatically at fine scales and, often, many small patches (<20 m²) of one association are scattered throughout a larger patch of another. Examples include the scattered patches of *Boehmeria* - *Macropiper* throughout the *Dracophyllum* - *Metrosideros* along the east side of Mount Lidgbird or the *Dracophyllum*-*Metrosideros* areas within the *Cleistocalyx* - *chionanthus* region in the Erskine Valley (personal observations). The majority of the island is covered in dense forest of various kinds, however, there are a number of more exposed sites, as well as the offshore islets, where

scrub (e.g., the *Melaleuca-Cassinia* alliance) and grassland (the *Poa* alliance) dominate (personal observations; Pickard 1983).

First discovered in 1788, settlement of the island began in the 1830's, it is now inhabited by around 300 permanent residents with as many as 400 visitors at any one time (Hutton, et al. 2007; Pickard 1983). Although there has been extensive clearing of the lowland areas for settlement, the vegetation of the Northern hills and the southern mountains has remained virtually untouched. Overall, less than 15 percent of the forests have been cleared and less than 20 percent of the vegetation is disturbed (Auld and Hutton 2004; Pickard 1983). The first botanists arrived on the island in 1853, providing an invaluable record of the flora's recent history (Pickard 1984). Although three species of bird have been hunted to extinction, the main cause of declines in native species appears to be the introduction of exotic biota (Auld and Hutton 2004; Hutton, et al. 2007). Consumption by introduced animals is likely to have caused the extinctions of two plant species (Auld and Hutton 2004). Pigs and feral goats had only locally significant impacts on vegetation (Pickard 1976) and these species, as well as feral cats, are now believed to be absent from the island due to eradication programs (Auld and Hutton 2004; Hutton, et al. 2007). The extinctions of further five bird species, and one subspecies, have been attributed to the introduction of ship rats in 1918 (Hutton, et al. 2007). Rats are believed to be the cause of the disappearance of two invertebrate species from the main island and severe declines in population numbers of the only two native lizards (Case 1991) and an endemic worm species (Hutton, et al. 2007). Several plant species suffer from heavy predation of seeds and fruits and others, mainly the palm species, receive stem damage and loss of seedlings, however the impact of this on the ecology of the island is poorly understood (Auld and Hutton 2004).

To date, 230 plant species have been introduced to the island (Hutton, et al. 2007; Pickard 1984), 45 of these appear to be having an impact on native species and the structure of the ecological communities (Auld and Hutton 2004; Hutton, et al. 2007). The secondary damage caused by removing hardy plants to expose more fragile rainforest to strong, salty winds appears to be one of the greatest threats to the islands native wildlife as it both damages the native flora and allows invasive species to get a foothold (Auld and Hutton 2004; Pickard 1983). Despite these problems, the majority of the island's vegetation has not been severely damaged as threats are localised to certain areas of the island or affect particular species (Auld and Hutton 2004; Brown and Baker 2009; Hutton, et al. 2007; Pickard 1983). In recent decades, a great deal of human effort has been invested in preserving the island's unique ecosystem; removal of invasive plant species has been a priority of the local government for some time and efforts are underway to eradicate the rat population (Department of Environment and Climate Change NSW 2007).

Why Study Speciation on LHI?

The Island's wildlife is incredibly diverse and unique; in some groups of the 1600 invertebrate species endemism is as high as 60% (Department of Environment and Climate Change NSW 2007) and the LHI flora comprises 242 vascular plant species of which 90 are endemic (Green 1994). Aside from this diversity and distinctiveness of the LHI flora and fauna there are several other characteristics of LHI that make it an excellent site for research into sympatric speciation. Having formed as a result of a volcanic eruption, the island has never

been connected to other landmasses by land bridges. Combined with the extreme isolation and small size of the island this is believed to make repeated colonisation by the same species, or by close relatives, improbable (Papadopoulos, et al. 2011; Savolainen, et al. 2006a). Furthermore, the small size of LHI reduces the possibility that sister species have ever been completely geographically isolated from each other particularly in organisms with efficient dispersal modes (Kisel and Barraclough 2010; Papadopoulos, et al. 2011). Overall, these properties of the island present an unusually appropriate set of circumstances for the identification of sympatric speciation events (Papadopoulos, et al. 2011; Savolainen, et al. 2006a; Savolainen, et al. 2006b), although this has been disputed (Stuessy 2006b). Due to the young age of the island, any speciation events on LHI are likely to have occurred relatively recently in evolutionary time, facilitating the investigation of factors that may have promoted divergence. Some genera that have speciated on LHI have diversified into similar ecotypes in other island systems (e.g., *Metrosideros polymorpha* and *Coprosma* species in Hawaii), raising the possibility that these island systems may also harbour cases of parallel speciation in plants. The recent discovery of so many sympatric speciation events of the island provides an opportunity to investigate how natural selection has caused different reproductive barriers to evolve in a diverse array of taxa under similar ecological conditions.

CONCLUSION

Although it is still a source of scientific debate, a growing body of evidence suggests that sympatric speciation can occur in island plants via speciation with gene flow as well as through homoploid hybrid speciation and, less controversially, polyploid speciation. The evidence seems to point to a significant role for sympatric speciation in island evolution and we are tantalisingly close to an answer. What has become clear is that all three mechanisms operate to some extent in the island floras that have been examined, however, the basic phylogenetic, population genetic and ploidy level data is often lacking to make complete assessments. Polyploid series are generally rare in the floras assessed and thorough assessment of hybrid speciation has been largely ignored. Repeatedly, the same taxonomic groups have diversified in different island systems suggesting that plants and certain genera in particular may be prone to ecologically driven speciation, in some cases suggesting that parallel speciation may have taken place (a similarly understudied phenomenon in plants; Ostevik, et al. 2012). There is still a great deal we do not know about the mechanisms and processes leading to within island speciation and systems like LHI offer the opportunity to tackle many unanswered questions.

Riyadh, Kingdom of Saudi Arabia

ABSTRACT

Gazelles are distributed across Africa and Asia and are adapted to arid and semi-arid environments. In this chapter, we discuss potential factors promoting the divergence of lineages within this group (*i.e.*, speciation events). The most recent common ancestor of gazelles is thought to have emerged during the Miocene (12–14 Ma) and to have split into the extant genera *Nanger* and *Eudorcas* (both endemic to Africa), *Antelope* (endemic to Asia), and *Gazella* (present in Africa, the Middle East and Asia). Within *Gazella*, two major clades are thought to have evolved allopatrically: (1) a predominantly Asian Clade (*G. bennettii*, *G. subgutturosa*, *G. marica*, *G. leptoceros*, and *G. cuvieri*) and (2) a predominantly African Clade (*G. dorcas*/ *G. saudiya*, *G. spekei*, *G. gazella*, and *G. arabica*). At present, both clades meet in North Africa and, especially, in Arabia. Other splits in this group are better explained by adaptive speciation in response to divergent ecological selection. In both clades, parallel evolution of sister species pairs (a desert-adapted form and a humid mountain-adapted form) can be inferred; desert-dwelling *G. dorcas* in Africa and *G. saudiya* in Arabia have a sister group relationship with mountain-dwelling *G. gazella* in the Levant and *G. arabica* in Arabia. This relationship exists within Africa between the desert-dwelling slender-horned gazelle (*G. leptoceros*) and the mountain-dwelling Cuvier's gazelle (*G. cuvieri*) of the Atlas Mountains. A third species pair occurs in Asia; desert-dwelling goitred gazelle (*G. subgutturosa*) and mountain-dwelling chinkara (*G. bennettii*). These (ecological) speciation events correlate with ecology and behavior: the mountain forms being browsers, sedentary, territorial, and living in small groups, while the desert forms are grazers, migratory/ nomadic, non-territorial, and living in herds. Furthermore, cryptic sister species (*G. gazella*, *G. arabica*), with strikingly similar phenotypes, exist within presumed '*G. gazella*', alluding to a possible

allopatric origin of this divergence following an isolation of humid mountain regions during hyper-arid phases. On the other hand, phenotypes within *G. arabica* tend to be variable, but are difficult or impossible to distinguish genetically.

INTRODUCTION

The earliest known fossil antelope, found in the Baringo Basin, Kenya, is of early Miocene origin (Thomas 1981), but it is uncertain where gazelline antelopes first emerged: in Africa, as proposed by Kingdon (1988), or in Asia, as suggested by Vrba and Schaller (2000). One of the four extant genera (*Antilope*) that evolved from these ancestors is in Asia, two (*Nanger* and *Eudorcas*) are in Africa, and one (*Gazella*) is on both continents as well as on the Arabian Peninsula. To understand the present distribution of gazelles (*i.e.*, *Antilope*, *Gazella*, *Nanger* and *Eudorcas*) it is important to interpret results from phylogenetic analyses in light of the geological and climatological history of the entire historic ranges of these genera.

The Arabian Peninsula is a prime example of a biogeographic transition zone, as it connects the floral and faunal regions of Africa and Asia (Vincent 2008). The present pattern is predominantly the result of the Afro-Eurasian species interchanges following the joining of the northern edge of the Afro-Arabian continent with Eurasia in the mid-Oligocene (ca. 30 Ma; Tchernov 1988; Bosworth et al. 2005; Vincent 2008). At the beginning of the Neogene (23 Ma), the Tethys acted as a substantial geographic barrier between Eurasian and Afro-Arabian faunas (Bernor 1983), leading to great divergence between these two realms and the evolution of two unique biotas (Tchernov 1988). The first major faunal interchange between Eurasia and Africa took place at the Proboscidean Datum Event (ca. 20 Ma; Madden and Van Couvering 1976), when a new land bridge (*i.e.*, the Gomphotherium Land Bridge; Rögl 1999a) connected Africa and Asia, and the Mediterranean Sea was isolated from the Indian Ocean for the first time.

The following faunal exchange was not continuous though, and was intensified during two main dispersal events in the Miocene at ca. 18–19 Ma and ca. 16–17 Ma (Thomas 1985; Rögl 1999b), interrupted by a re-opening of the seaway between Arabia and South Anatolia (Rögl 1999a). Evidence for faunal exchange during the first phase can be found in the Jibal Hadruk formation in Saudi Arabia (about 19 Ma) which contains fossil representatives of north-Tethyan fauna (Rögl and Steininger 1983). Before the connection to Eurasia was formed, the Arabian Peninsula supported an African fauna. After connection, Palearctic faunal elements appear in Arabia (Tchernov 1988; Delany 1989). During the early Miocene, extensive rifting of the Rift Valley resulted in a dramatic increase in water depth of the Red Sea, thus separating Arabia from Africa (Bosworth et al. 2005). During this period, savannah and steppe ecosystems expanded, leading to a radiation of grasses (Poaceae) followed by the rise of hypsodont ungulates (Strömberg 2011) and a rapid radiation of several tribes of bovids (Matthee and Robinson 1999). Although Africa became seemingly isolated from the northern hemisphere by the Saharo-Arabian arid belt in the late Miocene, faunal exchange of mammals increased once savannah- and desert-adapted forms evolved and the arid belt became a less effective barrier to the dispersal of such species (Thomas 1979; Tchernov 1988).

In the late Miocene/ early Pliocene era, the “savannah-mosaic” assemblages of Mesopotamia were already populated with representatives of the tribe Antilopini (*e.g.*, *Gazella deperdita* and *G. rodleri*) and other ungulates (Bernor 1986). The Miocene/ Pliocene boundary

was characterized by the onset of the Messinian Salinity Crisis (6 Ma), when the Mediterranean Sea became isolated from the Atlantic ocean and water levels regressed dramatically (Krijgsman et al. 1999). This resulted in an accelerated faunal interchange between Africa and Eurasia (*e.g.*, Agusti et al. 2006), especially of savannah-adapted species (Hassanin and Douzery 1999).

Following the Messinian Salinity Crisis the Mediterranean Sea reconnected to the Atlantic Ocean (Hilgen and Langereis 1988). At the same time, there was inflow of marine water into the Red Sea through the Bab el-Mandeb Strait, severing the connection between Arabia and the Horn of Africa (Bosworth et al. 2005). Furthermore, the orogeny of the Zagros Mountains—as part of the Alpine-Himalayan Mountain Belt—hampered biotic exchanges between Arabia and Asia (Tchernov 1988). All these factors led to an increasing isolation of Arabian fauna from Africa and Eurasia.

Moreover, the Afro-Arabian land bridge via the Sinai Peninsula became less permeable to faunal exchange due to a pull-apart basin development along the Aqaba-Levant Transform Fault (Bosworth et al. 2005). It remains uncertain as to whether there was a reconnection of both regions via the Bab el-Mandeb after the Miocene (Wildman et al. 2004; Winney et al. 2004; Fernandes et al. 2006; Bailey et al. 2009; Fernandes 2009). Climatic conditions during this time are thought to have caused a small-scale mosaic of ecosystems in the region (Tchernov 1988). Especially in Africa, faunal and palaeo-climatic records indicate shifts towards increasingly variable (and, on average, drier) conditions during the Plio-/ Pleistocene (2.8 Ma), allowing arid-adapted taxa to become more abundant (Thomas 1979; DeMenocal 2004).

In the Pleistocene the biotic interchange between Arabia and the Sahara was more asymmetric. Asian species, being more adapted to moister (mountainous) conditions, dispersed more easily into Arabia and North Africa along the mountain ridges of Arabia and the Sinai. By contrast, for arid-adapted Saharan species it was more difficult to invade the more humid parts of Asia (Delany 1989). Firstly, Saharan species on their way to Asia needed to cross the Nile Delta, which developed after the Messinian Salinity Crisis (Stanley and Warne 1998). Secondly, only the narrow stretch of sand dunes along the northern Sinai served as a suitable dispersal corridor for species adapted to hyper-arid conditions (Ferguson 1981). In addition, dispersing species would have needed to cross the Aqaba-Levant Transform Fault on their passage from the eastern Mediterranean towards Asia (Tchernov 1988).

The coastal plains of Arabia and the Sinai Peninsula experienced eustatic sea-level fluctuations, and large parts were submerged during inter-glacial periods (Chappell and Shackleton 1986; Shackleton 1987; van Andel 1989; Lambeck and Chappell 2001). During the Holocene (*i.e.*, after the glacial cycles) the geological situation remained more or less stable, and mammalian species in Arabia and surrounding areas—particularly gazelles—were increasingly impaired by human activities. Archeological evidence suggests that hunting by humans in prehistoric times was already having a major impact on populations of gazelles (Legge and Rowley-Conwy 1987; Bar-Oz et al. 2011).

In this section, we have provided a brief overview of the geological and climatological setting in which the evolution of extant gazelle species took place. In the following, we consider the question of how the above-mentioned factors influenced speciation in this group. We concentrate on possible scenarios for the modes of speciation, and discuss evidence for both allopatric and ecological speciation.

Table 1. List of specimens included in the phylogenetic analyses, their collectors/ accession numbers, and source of sequence. Abbreviations: EEZA – Estación Experimental de Zonas Áridas, Almería, Spain; KKWRC – King Khalid Wildlife Research Centre; OCE – Office for Conservation of the Environment, Muscat, Oman; WASWC - Wadi Al-Safa Wildlife Centre, Dubai, United Arab Emirates

MAJOR CLADES OF GAZELLES

Gazelles are members of the tribe Antilopini. Although the other members of this tribe are not part of this review, they are worth mentioning since they are considered to represent highly derived descendants of gazelle-like ancestors (Gentry 1992). Today the tribe Antilopini comprises as many as 13 genera (*Raphiceros*, *Ourebia*, *Madoqua*, *Dorcatragus*, *Saiga*,

Litocranius, *Ammodorcas*, *Antidorcas*, *Procapra*, *Eudorcas*, *Nanger*, *Antilope* and *Gazella*; Effron et al. 1976; Gentry 1992; Rebholz and Harley 1999; Groves 2000; Grubb 2005; Groves and Grubb 2011; Hassanin et al. 2012), four of which are traditionally labeled ‘true gazelles’, i.e., the genera *Gazella*, *Antilope*, *Nanger*, and *Eudorcas* (von Boetticher 1953; Groves 1985, 1988, 2000; Groves and Grubb, 2011).

To infer the phylogeny of gazelles, we investigated sequence variation of the mitochondrial cytochrome *b* gene of 17 taxa (including newly sequenced and already published data, see Table 1) covering all four gazelle genera, as well as the genera *Antidorcas* (springbok) and *Litocranius* (gerenuk). Bayesian analysis was performed in BEAST 1.5.2 (Drummond and Rambaut, 2007); no outgroup was defined beforehand. We used molecular clock data estimates inferred for *Gazella dorcas*. For methodological details see Lerp et al. (2011). jModelTest 0.1.1 (Posada 2008) uncovered HKY + Γ as the best fitting substitution model. We ran a Metropolis coupled Monte Carlo Markov chain (MC3) for 15 million generations with a burn-in phase of 1.5 million generations.

The phylogenetic tree inferred from this analysis is shown in Figure 1. High statistical support [i.e., posterior probability (PP) greater than 0.9] was found for the monophyly of gazelles (i.e., the genera *Antilope*, *Eudorcas*, *Gazella* and *Nanger*), but our analysis could not unambiguously resolve whether *Antidorcas* or *Litocranius* is the extant sister genus to the gazelles. Our findings are congruent with the results from a recent phylogenetic investigation of the order Cetartiodactyla by Hassanin et al. (2012), who analyzed the complete mitochondrial DNA sequence information, but included fewer gazelle taxa. Within the gazelles, all four genera were well supported as forming monophyletic clades, although the exact relationship among those genera could not be resolved. Time estimates for the first emergence of gazelles (95% credibility interval: 10.5–6.3 Ma), based on a molecular clock, were statistically not well supported (PP = 0.68), but are comparable to those provided by Hassanin et al. (2012), who estimated 8.5 ± 1.3 Ma (mean $\pm$ SD) for the corresponding phylogenetic split. During this time (i.e., in the late Miocene) savannah and steppe ecosystems with xerophytic shrub-land expanded into eastern and northern Africa and onto Arabia (Pound et al. 2011). This expansion of grasslands, together with the subsequent diversification of grasses (Strömberg 2011), probably facilitated the remarkable diversification (i.e., radiation) of antelopes at this time.

In contrast to paleontological studies describing the earliest fossil Antilopini from the middle Miocene in Africa (14 Ma; Vrba 1985) our molecular estimates for the first appearance of gazelles are considerable younger (10.5–6.3 Ma). How can these contrasting findings be reconciled? First of all, phylogenetic analyses through the analysis of sequence variation are based on extant taxa only, so extinct clades typically go undetected unless analyses of ancient DNA are feasible. Also, inference of time estimates from molecular phylogenetic approaches—as was done in this study—depend on the settings (i.e., substitution model and rates) for the molecular clock. Here, we used no fossil calibration points as constraints for our analysis (see below), but found similar time estimates as described by Hassanin et al. (2012), who used six calibration points from the fossil record for estimating the diversification of the entire order Cetartiodactyla. We are, therefore, confident that the settings of the molecular clock used in this study were realistic. Secondly, the classification of fossils is based on morphological measurements, especially with respect to skull and horn morphology. Gazelles show character state combinations that are likely plesiomorphic for the entire subfamily Antilopinae or, perhaps, even for the entire family Bovidae, which first appeared in the early Miocene (Gentry

1992; Vrba and Schaller 2000). Such morphological parallelisms and the incomplete fossil record render taxonomy within the Bovidae difficult (Vrba 1985; Gentry 1992). In addition, some bovid fossils showing this plesiomorphic character state combination are likely misclassified and falsely described as belonging in the vicinity of the genus *Gazella*.

The divergence of gazelles (PP = 1; 95% credibility interval: 8.0–4.8 Ma)—ultimately leading to the four extant genera in a relatively short period of time (Fig. 1)—could have been promoted by climate change following the Messinian Salinity Crisis (~6 Ma). Conditions were generally dryer (DeMenocal 2004), and new and larger areas became inhabitable for arid-adapted antelopes. The ancestors of the genus *Antilope* seem to have reached Asia by this time (Khan et al. 2006). The occurrence of blackbuck (*Antilope cervicapra*)—the only extant species of this genus—is still restricted to the Indian subcontinent and might be a descendant of this first expansion wave. Today, the descendants of *Eudorcas* and *Nanger* occur exclusively in Africa, and it remains doubtful if these genera ever occurred outside Africa.

The situation within genus *Gazella*, however, is more complex, because extant species occur both in Africa and Asia, as well as in Arabia (Kingdon 1988; Gentry 1992). Two major clades, with a well-supported monophyly, are inferred by our present study; their split is estimated at 3.9–2.3 Ma, i.e., in the Pliocene (Fig. 1). The ‘African Clade’, comprises more species, endemic to Africa, whereas the ‘Asian Clade’ is predominantly in Asia. Both clades, however, comprise taxa that occur on the “opposite” continent (Fig. 1).

The African Clade contains Speke’s gazelle (*G. spekei*), which is endemic to the Horn of Africa in Somalia (East 1999), dorcas (*G. dorcas*), mountain (*G. gazella*) and Arabian gazelles (*G. arabica*; Effron et al. 1976; Rebholz and Harley 1999; Wronski et al. 2010; Bärmann et al. 2012; this study). The diversification of the African Clade started 2.8–1.6 Ma ago (early Pleistocene; Fig. 1). By far the widest distribution range within this clade is that of *G. dorcas*, which includes large parts of northern Africa and, once, much of Arabia (where described as Saudi gazelle *G. saudiya*; Carruthers and Schwarz 1935; Rebholz et al. 1991; Rebholz and Harley 1997; Hammond et al. 2001). Together with *G. gazella* and *G. arabica*—which also inhabit the Arabian Peninsula—this is the most eastern extent of the range of the African Clade. We hypothesize that *G. dorcas* represents the ancestral character state combination of the African Clade because cytogenetic and morphological data showed *G. dorcas* to be basal to several species within *Gazella* (Lowenstein 1986; Gentry 1992; Vassart et al. 1995b). Moreover, it is suggested that the Antilopini evolved as grazers in the open, semi-desert and desert habitats of Africa (Kingdon 1988; Hassanin et al. 2012) and that the dispersal into mountainous and more humid habitats represents a shift associated with speciation events. At the edges of its distribution range, *G. dorcas* seems to have split rapidly into *G. spekei* and *G. gazella*, leaving sister group relations of these three species unresolved. This diversification was probably the result of ‘ecological speciation’ (see below). Lerp et al. (2011) found support for the idea that *G. dorcas* colonized Arabia via the Sinai and not via the Bab el-Mandeb. Thus, great distance and the Red Seas likely separated the ancestors of today’s *G. arabica*, *G. gazella* and ‘*G. saudiya*’ of Arabia from Africa’s *G. spekei* and *G. dorcas*.

Figure 1. Phylogeny based on the alignment of the complete sequences of the cytochrome *b* gene. Bayesian analysis was performed with 41 sequences with the HKY + Γ substitution model. Only posterior probability values larger than 0.9 are reported. Node bars represent the 95% credibility intervals of the divergence times of statistically supported phylogenetic splits. Symbols of Africa and Asia indicate the occurrence of single species on that continent. Within the genus *Gazella*, a mountain symbol indicates a more humid and/or mountainous habitat, whereas a grass symbol indicates open savannah/ desert habitat.

Within the Asian Clade the majority of species are distributed on the Asian continent. The divergence time of this clade is estimated as 2.9–1.6 Ma ago and is comparable with the diversification of the African Clade of the genus *Gazella*. Therefore, the early Pleistocene is when most of today's species of *Gazella* emerged. We hypothesize that the diversification of the Asian Clade occurred in central Asia after the first (smaller) gazelles appeared, probably in the late Pliocene. The Asian Clade consists of *G. subgutturosa* and *G. bennettii*, both forming a reciprocally monophyletic clade in our present phylogeny. Both species occur in central Asia and India. Other members of the Asian Clade include *G. marica* and the African *G. cuvieri* and *G. leptoceros*, which together form a highly supported monophylum (Hammond et al. 2001; Wacher et al. 2010; Fig. 1). Changing climatic and geological conditions at the beginning of the Pleistocene could have enabled the ancestors of *G. marica* to cross the Zagros Mountains and invade the Middle East, where they occurred sympatrically with gazelles from the African Clade. Pliocene and early Pleistocene fossils of gazelles found in Turkey support this hypothesis, because they are distinct from fossils of *G. gazella* from the same period (Sickenberg 1975). Later (1.4–0.7 Ma ago) members of the Asian Clade crossed the Sinai Peninsula and Nile River to enter Africa and evolve into *G. leptoceros* which, today, occupies a habitat type similar to that of *G. marica* (i.e., the sand dunes and gravel plains of northern Africa; Harrison 1968; Devillers et al. 2005).

EXTANT SPECIES OF SMALLER GAZELLES

Before we elaborate on the mechanisms of speciation within the group of smaller gazelles (genus *Gazella*), we provide a brief overview of the historical and current distribution patterns as well as the current threats to the survival of the nine extant species in this group.

Dorcas gazelles (*G. dorcas*) were originally distributed from Morocco and Mauretania eastwards to the Horn of Africa, Sinai Peninsula, the Levant (Yom-Tov et al. 1995; East 1999; Hammond et al. 2001) to east of the Hejaz and Asir Mountains of western Arabia. This species was extirpated from Arabia about 30–40 years ago (Vesey-Fitzgerald 1952; Thouless et al. 1991; Habibi and Williamson 1997). With the exception of Israel and Ethiopia, numbers are decreasing rapidly and populations are increasingly fragmented (Smith 1999; Mallon and Kingswood 2001; Lafontaine et al. 2005). This decline is estimated at >30% over three generations, with less than 25% of the remaining animals living in protected areas, resulting in the IUCN status 'Vulnerable' (Mallon and Kingswood 2001; IUCN/SSC Antelope Specialist Group 2008a).

Mountain gazelles (*G. gazella*) are distributed from the eastern Turkey and Lebanon, through Palestine, Golan and western Jordan. Previously lumped with the Arabian gazelle (which we refer to as *G. arabica*—see below), which ranged over the Arava Valley in southern Israel, western Saudi Arabia, Yemen, Oman and United Arab Emirates. The number of *G. arabica* has declined dramatically during the past 50 years (Thouless and Al Bassri 1991; Magin and Greth, 1994; Mallon and Kingswood, 2001). Extensive hunting, habitat loss, and population fragmentation are principal causes of decline (Thouless et al., 1991; Magin and Greth 1994; Mallon and Kingswood 2001). The IUCN category is 'Vulnerable' based on *G. gazella* plus *G. arabica* (Mallon and Kingswood 2001; IUCN/SSC Antelope Specialist Group

2008b). The situation for *G. gazella* from northern and central Israel is less critical (Clark and Frankenberg 2001).

Speke's gazelle (*G. spekei*) is endemic to the Horn of Africa, occurring in Somalia from the Indian Ocean westwards to the Gulis Range (Heckel et al. 2008). Although traditionally not hunted by people, numbers have collapsed over the last 20 years due to uncontrolled hunting by soldiers (Heckel et al. 2008). Probably the species is extirpated from Ethiopia. No effective protection is in place for *G. spekei*. The IUCN status is 'Endangered' (Heckel et al. 2008).

Goitred gazelle (*G. subgutturosa*) occurs east of the Tigris/ Euphrates Basin, north into the Caucasus and across Iran into Turkmenistan. Following the steppes of central Asia, *G. subgutturosa* inhabits the Takla Makan, Tarim Basin and Sianking of China and extends farther eastwards to central Mongolia, where it is replaced by the Mongolian gazelle (*Procapra gutturosa*; Groves 1985; Kingswood and Blank 1996; Mallon and Kingswood 2001; Zachos et al. 2010). Large populations occurred over a vast area until recently with ca. 100,000 individuals in the early 1990's (Mallon and Kingswood 2001). Hunting and habitat loss have caused a decline of >30% over the last ten years in many populations, resulting in the IUCN status 'vulnerable' (Mallon 2008a). The example of Mongolia should be highlighted, since a substantial proportion of the global population of *G. subgutturosa* once lived there, but heavy poaching, following collapse of the communist regime, has eliminated most of the large herds, resulting in a population decline >50% (Mallon 2008a).

The chinkara (*G. bennettii*) occurs in western and central India (especially in the Thar Desert), in the arid regions of Baluchistan and Sindh Provinces in Pakistan, south-western Afghanistan and north-central Iran (Rahmani 1990, 2001; Habibi 2001; Karami et al. 2002; Mallon 2008b). Scattered populations are also found in the sub-mountainous tracts of Punjab (Roberts 1977; Habibi 2001). Although numbers in Pakistan and Iran are decreasing due to overhunting (Mallon 2008b), the population in India is >100,000 (Rahmani 2001). Despite the large number of people in India, antelope populations there are relatively stable. This is mainly the result of an extensive network of protected areas coupled with low hunting pressure (Mallon and Kingswood 2001). *G. bennettii*, in particular, is secure in the Thar Desert with 80,000 individuals (Rahmani 2001) and, furthermore, is protected in reserves or by local people (Mallon and Kingswood 2001). For these reasons, *G. bennettii* is the only *Gazella* sp. that is not threatened (IUCN status 'least concern'; Mallon 2008b).

The sand gazelle (*G. marica*) is found in open habitats of the Middle East from the Tigris/ Euphrates Basin in Iraq, through Jordan and Syria into southern Turkey, and southwards through much of Arabia (Wacher et al. 2010). Current distribution is limited to a few (protected) areas in the United Arab Emirates, Oman, Syria, Turkey, probably in Jordan and perhaps western Iraq (Kasperek 1986; Mallon and Kingswood 2001; Massolo et al. 2008). In Saudi Arabia, *G. marica* is probably extinct outside of two protected areas Mahazat as-Sayd and Uruq Bani Ma'arid, both of which harbor reintroduced populations (Cunningham and Wacher 2009). There are probably <10,000 mature individuals and the population trend is downwards (IUCN/SSC Antelope Specialist Group 2008c). A good number of *G. marica* occur in captivity and are available for re-introductions (Cunningham and Wacher 2009). The current IUCN status is 'Vulnerable' (IUCN/SSC Antelope Specialist Group 2008c).

Slender-horned gazelle (*G. leptoceros*) is endemic to the sand dunes (ergs) of the Sahara, west of the Nile River (Devillers et al. 2005). Until recently, two subspecies were distinguished, i.e., *G. l. loderi* from the sand deserts of Tunisia, Algeria and Libya, and *G. l. leptoceros* from the Western Desert in Egypt (Devillers et al. 2005). However, phylogeographic analyses for

validating these subspecies are lacking (Mallon et al. 2008). Numbers of *G. leptoceros* have decreased severely in the past decade due to hunting, especially in Egypt (Saleh 1987; Mostafa 2005), but also to habitat loss (Devillers et al. 2005). The conservation status of *G. leptoceros* in Mali, Niger, Chad and Libya is not known, but numbers are probably low (Devillers et al. 1999, 2005). All known populations are small to very small. The IUCN degree of threat status is ‘Endangered’ (Mallon et al. 2008).

Finally, Cuvier’s gazelle (*G. cuvieri*) is endemic to the Atlas Mountains and neighboring ranges in Morocco (including the lowlands in the west), Algeria and Tunisia (Lafontaine et al. 1999; Beudels-Jamar et al., 2005). As for most *Gazella* spp., hunting is the major threat to the species and has caused a sharp population decline since the 1930’s (Lafontaine et al. 1999; Beudels-Jamar et al. 2005). Habitat loss and degradation have also contributed to this decline (Sellami et al. 1990; de Smet 1991, 1994; Beudels-Jamar et al. 2005). There are currently ca. 2,500 individuals in several fragmented populations. The IUCN status is ‘Endangered’ (Mallon and Cuzin 2008). Some populations recently reported to be stable or even increasing (Mallon and Kingswood 2001; Mallon and Cuzin 2008).

PARALLEL, ADAPTIVE SPECIATION OF SPECIES PAIRS

Within both clades of genus *Gazella*, species pairs exist that exhibit parallel specializations in trophic ecology and social organization: On-the-one-hand, there are species more adapted to open, hot dry deserts. These species likely represent the ancestral character state combination. These species tend to be grazers, form herds and migrate. On-the-other-hand, species adapted to a more humid climate, are browsers that live in small groups and are sedentary and territorial. Our phylogenetic analysis infers three such species pairs (i.e., *G. dorcas* vs. *G. gazella* plus *G. arabica*; *G. subgutturosa* vs. *G. bennettii*, and *G. leptoceros* vs. *G. cuvieri*), where three lineages of desert-adapted forms independently diverged into a browsing, mountain-dwelling form, and a grazing, desert- or savannah-dwelling form. Even though we lack a plausible explanation as to how adaptation to different habitat types promoted reproductive isolation in gazelles, we argue that these three splits represent ecological speciation events.

Schluter and Nagel (1995) presented three—rather strict—prerequisites for parallel ecological speciation to occur; “(1) separate populations in similar environments must be phylogenetically independent [...], (2) ancestral and descendant populations [...] must be reproductively isolated, and (3) separate descendant populations inhabiting similar environments must not be reproductively isolated from one another”. This concept is particularly useful when considering contemporary parallel speciation within the same species, as indicated by the third criterion. When trying to apply the concept of parallel speciation to the phylogeny of gazelles it needs to be interpreted in a slightly broader sense. Point (3) of Schluter and Nagel’s (1995) definition is not met, as speciation in response to adaptation to a more humid climate occurred, independently, three times, and at different times, in different geographical regions, and from different ancestral species.

The oldest split of an ecologically divergent species pair inferred from our phylogenetic analysis is between *G. dorcas* and *G. gazella*/*G. arabica*. This split occurred 2.8–1.6 Ma (late Pliocene; Fig. 1). *G. dorcas* are grazers that inhabit Sahelian savannahs as well as semi-arid gravel and sand deserts, while avoiding hyper-arid areas and the upper elevations of the central-

Saharan massifs (Yom-Tov et al. 1995; Wachter et al. 2004). This species usually forms small family groups of 5–12 individuals (Yom-Tov et al. 1995), but during migration form herds of more than 100 individuals (Haltenorth and Diller 1977). *G. gazella* and *G. arabica*, by contrast, are sedentary, live in very small groups (two to maximal 20 individuals), live in upland areas of broken terrain on the Arabian Peninsula and the Levant, and adult males defend territories (Walther et al. 1983; Mendelssohn et al. 1995; Martin 2000; Wronski and Plath 2010). *G. dorcas* can cope without surface water by relying on hygroscopic food and respiratory water (Yom-Tov et al. 1995), whereas *G. gazella* and *G. arabica* prefer to drink on a regular basis (Mendelssohn et al. 1995). *G. dorcas* are reproductively isolated from *G. gazella*, and their hybrids are sterile or at least sub-fertile (Mendelssohn et al. 1995).

The second ecologically diverged species pair is *G. subgutturosa* and *G. bennettii*. Divergence probably occurred ca. 2.4–1.3 Ma ago (late Pliocene/ early Pleistocene) but statistical support for this date is weak (PP=0.89). *G. bennettii* are adapted to sand dune areas, regolith plains and hilly regions up to 1,500 m above sea level. This species avoids flat and steep terrain, and is typically on the edge of deserts (Roberts 1977; Sharma 1977; Rahmani 1990; Karami et al. 2002). *G. bennettii* are sedentary and live in groups of one to three individuals, but sometimes in larger herds (Rahmani 1990; Bagchi et al. 2008). Males form territories that they defend vigorously (Walther et al. 1983). The species is typically a browser, but during the rainy season they also graze (Sharma 1977; Habibi 2001). Compared to *G. subgutturosa*—which meet their water needs entirely from hygroscopic food plants—*G. bennettii* are independent of surface water only in winter. In the hotter months, when temperatures are >40°C, they have to drink regularly (Habibi 2001). *G. subgutturosa* are grazers that can also browse on xerophytic bushes (Roberts 1977; Kingswood and Blank 1996; Karami et al. 2002). This species is semi-nomadic with males forming territories only during the rut (i.e., October–December; Kingswood and Blank 1996; Blank 1998; Bekenov et al. 2001).

The youngest split of an ecologically divergent species pair is between *G. leptoceros* and *G. cuvieri* and dates to 420,000–110,000 years ago (middle Pleistocene). The young age of this split (i.e., the small genetic divergence between them) raises doubt concerning their species status (Hassanin et al. 2012). Nonetheless, both species are morphologically readily distinguished (Gentry 1964; Groves 1969; Groves and Grubb 2011). *G. leptoceros* are desert-dwelling grazers (Louys et al. 2011; Smith et al. 2001), that occasionally browse on *Acacia* (Saleh 2001). The species is nomadic, crossing vast areas of flat, open desert in search of sparse, ephemeral grasses (Kingdon 1997; Saleh 2001; Smith et al. 2001). The typical group size is <15 individuals (Smith et al. 2001). In contrast, *G. cuvieri* inhabit dry forests and maquis of the semi-arid Mediterranean type (Sellami and Bouredjli 1991; Beudels-Jamar et al. 2005), browse on acorns and young leaves of legumes, but also graze (Kingdon 1997; Smith et al. 2001). They live up to 2,600 m above sea level where they are limited by snow in winter (Aulagnier et al. 2001; Beudels-Jamar et al. 2005). *G. cuvieri* need to drink on a regular basis (Smith et al. 2001; Beudels-Jamar et al. 2005). This species lives in groups of 5–8 individuals, but solitary individuals are common (Sellami and Bouredjli 1991; Kingdon 1997; Beudels-Jamar et al. 2005). Males are territorial during the rut (in winter; Sellami and Bouredjli 1991; Kingdon 1997; Smith et al. 2001).

A TAXONOMIC REVIEW OF THE GENUS *GAZELLA*

It has been repeatedly emphasized that the taxonomy of gazelles is one of the least resolved among mammals (Groves and Harrison 1967; Groves, 1969). No other genus of large mammals creates such problems with regards to its classification based on skull morphometry, phenotypic appearance and genetic information, as does *Gazella*. As such, many taxonomic revisions of this genus have been put forth (Lydekker and Blaine 1914; Ellerman and Morrison-Scott 1951; von Boetticher 1953; Gentry 1964; Groves and Harrison 1967; Groves 1969, 1985, 1988; Lange 1972; Rostron 1972).

While the taxonomy of *Antelope* and *Nanger* has not changed substantially in recent decades (von Boetticher 1953; Gentry 1964; Lange 1972; Groves and Grubb 2011) the taxonomy within *Eudorcas* and *Gazella* remains uncertain, and with recent molecular findings casting doubt on earlier classifications that are based on morphological and cytogenetic traits. Our phylogenetic analysis of *Gazella* supports the existence of nine species (*G. gazella*, *G. arabica*, *G. dorcas*, *G. spekei*, *G. bennettii*, *G. subgutturosa*, *G. marica*, *G. leptoceros* and *G. cuvieri*), most of which require further taxonomic clarification.

Gazella marica (Thomas 1897), was subsumed within *Gazella leptoceros* by Ellerman and Morrison-Scott (1951). Subsequently, *G. marica* was considered a subspecies of *G. subgutturosa* based on morphological and karyological similarity (Groves and Harrison 1967; Kingswood et al. 1996, 1997). In more recent studies the phylogenetic relationships between *G. subgutturosa* from east of the Euphrates/ Tigris Basin and from the Arabia (*G. marica*) were reanalyzed based on molecular genetic information (Hammond et al. 2001; Wachter et al. 2010) and supported *G. marica* as a species. This conflicted with the grouping pattern inferred from skull structure and horn conformation (Groves and Harrison 1967). *G. marica* appears to be most closely related to the North African species *G. leptoceros* and *G. cuvieri* (Hammond et al. 2001; Wachter et al. 2010; see above).

In case of *G. subgutturosa*, Vassart et al. (1995b) state that *Gazella* will be paraphyletic when this species is included, because *G. subgutturosa* could be a sister taxon of *Antelope*. Both taxa share two unique centric fusions in their chromosomes causing the need to revive the genus *Trachelocele* (Ellerman and Morrison-Scott 1951; Groves 1969). Other studies investigating morphology or mitochondrial sequence variation placed *G. subgutturosa* within *Gazella* and refute *Trachelocele* (Grubb 2005; Groves and Grubb 2011; Hassanin et al. 2012; this study). Due to morphological variation within *G. subgutturosa*, up to three species are proposed by Groves and Grubb (2011), but there are no empirical data to support this position.

Early classifications place *G. bennettii* as either a subspecies of *G. gazella* (Haltenorth and Diller 1977; Roberts 1977) or as a subspecies of *G. dorcas* (Gentry 1964; Groves 1969; Lange 1972). Karyological data, however, found *G. bennettii* to be unrelated to *G. gazella* (Furley et al. 1988; Kumamoto et al. 1995). Within *G. bennettii*, up to six species are proposed on the basis of morphological divergence (Hemami and Groves 2001; Groves and Grubb 2011), but, again, evidence justifying this division is lacking. In this study—where two of the proposed *G. bennettii* taxa were included—there was no indication of more than one species. Nevertheless, a phylogeographic study with individuals from the entire distribution range is highly warranted.

In the cases of *G. cuvieri* and *G. leptoceros* the taxonomic classification remains confusing. Lange (1972) classified *G. cuvieri* under *G. gazella*, while *G. leptoceros* was considered a subspecies of *G. subgutturosa*. Later, a karyological study showed that *G. cuvieri* is unrelated

to *G. gazella* (Kumamoto and Bogart 1984). Furthermore, a division of *G. leptoceros* into two subspecies (*G. l. loderi* and *G. l. leptoceros*) was suggested based on differences in distribution ranges and ecology (Devillers et al. 2005). In contrast, *G. marica* and *G. leptoceros* are recently proposed to be subspecies of *G. cuvieri* because of their relatively low mitochondrial sequence divergence (Hassanin et al. 2012).

Within *G. dorcas*, several subspecies are described on the basis of phenotypic variation, such as coat coloration and horn shape and length (Groves 1969, 1981; Alados 1987; Yom-Tov et al. 1995; Groves and Grubb 2011). A phylogeographic study based on sequence variation of the mitochondrial cytochrome *b* gene and control region recently indicates that *G. dorcas*—including ‘*G. saudiya*’ and ‘*G. pelzelni*’—represent a reciprocally monophyletic group with a sister-group relationship to *G. gazella* and *G. arabica* (Lerp et al. 2011). No statistically significant support was found for any geographic structure within the distribution range of *G. dorcas*. Nevertheless, keeping *G. dorcas*, ‘*G. saudiya*’ and ‘*G. pelzelni*’ separated at captive breeding centers is warranted as low genetic divergence at neutral markers does not preclude the potential existence of local adaptations (Hammond et al. 2001; Lerp et al. 2011).

Confusion over taxonomy and nomenclature at the species level has reached a maximum in *G. gazella* and *G. arabica* (Groves and Harrison 1967; Harrison 1968; Groves 1969, 1983, 1989, 1996, 1997; Lange 1972; Groves and Lay 1985; Vassart et al. 1995a; Greth et al. 1996; Vassart et al. 1996; Kingswood et al. 1997; Rebholz and Harley 1999; Wronski et al. 2010). At least four species (*G. gazella*, *G. bilkis*, *G. arabica*, and *G. erlangeri*) and eight subspecies have been named (Groves 1996, 1997; Grubb 2005; Groves and Grubb 2011). Based on the analysis of cytochrome *b* sequences of five *G. gazella* in the context of a phylogeny of the Antilopinae, Rebholz and Harley (1999) suggested that two genetically distinct lineages might exist: one from the Levant (Galilee to Turkey) and one from Negev and Arabia. Those findings have been confirmed in an analysis comprising more individuals from a larger area and more mitochondrial and microsatellite markers (Wronski et al. 2010; Lerp et al. 2013). This supports recognition of two ‘cryptic’ species in this clade, which may have evolved due to prolonged isolation or local adaptations to divergent environments (Wronski et al., 2010; Lerp et al. 2013). The nominate *G. gazella* was originally described as *Antilope gazella* (Buffon 1764) from the Levant. This raises the question of which species name to assign to the populations in Arabia. Recent molecular analyses of the cytochrome *b* gene from the type *G. arabica* (described as *Antilope arabica* Lichtenstein 1827) indicate that this taxon is invalid, because skin and skull of the type specimen of *G. arabica* did not form a separate lineage, but clustered with *G. gazella* (skin) and with *G. arabica* (skull; Bärmann et al. 2012). Following the rules of precedence (priority rule, International Code of Zoological Nomenclature, ICZN) the name *G. arabica* is available for gazelles in Arabia.

Within *G. arabica*, however, much taxonomic uncertainty remains. One of the most challenging questions is the status of *G. erlangeri*. Neumann (1906) described specimens from Lahadsch (Lahej), north of Aden, as a greyer form of *G. arabica*. He introduced a new subspecies name to account for this difference and cited the illustration labeled *G. arabica* in Sclater and Thomas (1898) as an accurate representation of what he was describing. Due to its putative sympatric distribution with *G. arabica*, Groves (1996) suggested full species status for *G. erlangeri*. Gazelles currently kept in captivity at King Khalid Wildlife Research Centre in Saudi Arabia and at Al Wabra Wildlife Preservation in Qatar show the described combination of diagnostic features and thus, were considered to represent *G. erlangeri* (Groves 1996)—even though the provenance of these gazelles is not known. Phylogenetic studies (using

mitochondrial markers) on these putative *G. erlangeri* cluster them amongst other *G. arabica* from all over Arabia (Hammond et al. 2000; Blacket et al. 2001; Hundertmark and Omer 2004; Wronski et al. 2010). In summary, it remains unsolved whether Neumann's (1906) *G. erlangeri* is a distinct taxon and how it relates to other gazelles.

Finally, the most enigmatic gazelle described from Arabia should be mentioned: the Queen of Sheba's gazelle (*Gazella bilkis*). Specimens shot in the Taizz Mountains of southern Yemen in 1951 (now stored at Chicago FMNH) were originally identified as *G. arabica erlangeri* by the collector Hoogstraal. They were, however, re-evaluated retrospectively based on skull morphology and described as *Gazella bilkis* (Groves and Lay 1985; Groves and Grubb 2011). Even though the taxonomic status of these gazelles remains unclear, there is no doubt that *G. bilkis* is extinct (Mallon and Al-Safadi 2001).

CONCLUSION

Gazelles comprise four monophyletic genera (*Antilope*, *Nanger*, *Eudorcas* and *Gazella*) and emerged in the early Miocene (10.5–6.3 Ma). While three genera are restricted to the continent on which they probably evolved (*Antilope* to Asia, *Nanger* and *Eudorcas* to Africa), the situation in *Gazella* is more complex, with extant species in Africa, the Middle East, and Asia. Different modes of speciation are apparent within *Gazella*: (1) allopatric speciation in two major clades, with one predominantly Asian Clade and the other a predominantly African Clade; (2) parallel, adaptive speciation of three species pairs in parapatry, with one representative being a grazing, desert- or savannah-dwelling, (semi-)nomadic form, and the other being a browsing, mountain-dwelling and mostly sedentary form; and (3) cryptic speciation following phases of geographic isolation, where two genetically distinct forms with similar phenotypes can be seen (*G. gazella* and *G. arabica*). In general, gazelles are characterized by pronounced phenotypic variability that is not always mirrored by molecular sequence divergence, and a part of this variation may be due to phenotypic plasticity. This led to taxonomical incongruence plainly expressed in the number of described species that reached a maximum in a recent book by Groves and Grubb (2011), with 36 extant gazelle species (including 1 species in the genus *Antilope*, 5 in *Nanger*, 6 in *Eudorcas* and even 24 in *Gazella*) being listed. In terms of conservation this situation is unfortunate. The taxonomical incongruence hampers conservation efforts regarding captive breeding or re-introduction programs, as it remains confusing which gazelles should be bred separately to preserve natural biodiversity. Further investigations using nuclear DNA markers of the extant taxa will be helpful to clarify the situation for critical taxa.

ACKNOWLEDGMENTS

We thank His Highness, Prince Bandar bin Saud bin Mohammed al Saud (The President, Saudi Wildlife Authority) for his permission to conduct research on wildlife in the Kingdom. We are particularly grateful to the many colleagues and institutions who have contributed to the large number of samples collected from many sites in Africa, the Middle East and Asia. In this regard, we thank Timothy Wachter, Robert L. Hammond, Tamar Ron, Saeed Mubarak,

Khalid Alageel, Mohammed Shobrak, Osama B. Mohammed, Iyad Nader, Andrew Spalton, Roni King, Kris Hundertmark, Nick Lindsay, Doug Williamson, Jamal M. Mansoor, Denny Maaz, the National History Museum, London, the Harrison Museum, the Powell-Cotton Museum, the Field Museum, Chicago, the Steinhardt National Collection of Natural History, Zoological Museum at Tel-Aviv University, the Office for Conservation of the Environment, Muscat, Oman, the Estación Experimental de Zonas Áridas, Almeria, Spain and Al Wabra Wildlife Preservation, Al Wabra, Qatar. Furthermore, we thank the two Laboratory technicians at King Khalid Wildlife Research Centre (William Macasero and Benito Flores) for their considerable efforts in extracting DNA from most of our samples.

Chapter 4

CHROMOSOME PLASTICITY, ADAPTATION AND SPECIATION IN MALARIA MOSQUITOES

Igor V. Sharakhov*

Department of Entomology, 203 Fralin Life Science Institute,
Virginia Tech, Blacksburg, VA, US

ABSTRACT

Nonrandom distribution of rearrangements is a common feature of eukaryotic chromosomes that is not well understood in terms of genome organization and evolution. In malaria mosquitoes, chromosomal inversions—genome rearrangements that flip chromosomal segments by 180°—are often highly nonuniformly distributed among five chromosomal arms. These rearrangements are associated with epidemiologically important adaptations and, possibly, speciation in mosquitoes. A fundamental question is whether the genomic content of the chromosomal arms is associated with inversion polymorphism and fixation rates. This chapter highlights important differences in evolutionary dynamics of the sex chromosome and autosomes and reviews data about association between characteristics of the genome landscape and rates of chromosomal evolution. Recent studies suggest that a unique combination of various classes of genes and repetitive DNA in each arm, rather than a single type of repetitive element, is likely responsible for arm-specific rates of rearrangements. Additional factors, such as spatial constraints imposed by the nuclear architecture, may be responsible for the nonuniform distribution of rearrangements. Another important question is whether polymorphic inversions on homologous chromosomal arms of distantly related mosquito species nonrandomly share similar sets of genes. The available data indicate that natural selection favors specific gene combinations within polymorphic inversions when distant species are exposed to similar environmental pressures. This knowledge could be useful for the discovery of genes responsible for an association of inversion polymorphisms with phenotypic variations in multiple species. In this chapter, I also review the literature about a possible role of heterochromatin in speciation of malaria mosquitoes. The existing data demonstrate the elevated evolutionary plasticity of the heterochromatic portion of the mosquito genome.

Finally, I discuss the importance of high-quality genome assemblies for reconstructing a gene order-based phylogeny and studying mosquito evolution.

INTRODUCTION

Malaria mosquitoes belong to genus *Anopheles*, which is the largest of the three genera, *Anopheles*, *Bironella*, and *Chagasia*. These genera make up subfamily Anophelinae, which belongs to Culicidae, Diptera. Genus *Anopheles* is further subdivided into subgenera, *Anopheles*, *Cellia*, *Kerteszia*, *Lophopodomyia*, *Nyssorhynchus*, and *Stethomyia*. More than 500 recognized species of genus *Anopheles* inhabit every continent except Antarctica. Taxonomic and population complexity is a common feature of malaria mosquitoes (Krzywinski, Besansky 2003). The rich biodiversity of malaria mosquitoes has the direct epidemiological implications. Of the ~500 anopheline species, no more than 30 significantly contribute to the malaria transmission. It is still not completely clear why some species or populations are efficient malaria vectors while others are of no medical importance. Therefore, understanding the adaptation and speciation in malaria mosquitoes has not only a theoretical interest for evolutionary biology but also practical applications for vector control. Comparative genomic analyses of vector competence and other epidemiologically important traits will be informative if performed within a phylogenetic framework. Inferring ancestral and derived genomic features in anophelines is crucial for identifying the evolutionary changes associated with the origin and loss of human blood choice, ecological and behavioral adaptations, and association with human habitats. Traditionally, reconstructions of the anopheline phylogeny have been done using morphological and molecular markers (Krzywinski, Wilkerson, Besansky 2001; Krzywinski, Besansky 2003; Harbach 2004). Available data support the monophyly of the six *Anopheles* subgenera, a sister-group relationship between subgenera *Nyssorhynchus* and *Kerteszia*, and a sister-group relationship between subgenera *Cellia* and *Anopheles*. If *Plasmodium falciparum* was transferred to the Americas by European colonialists in post-Colombian times, then the contact between *Nyssorhynchus* and *P. falciparum* (which is normally transmitted by *Cellia*) is very recent (Moreno et al. 2010). This supports the hypothesis that the susceptibility of mosquitoes to the malaria parasite is an ancestral trait, while the refractoriness to this parasite in nonmalaria vector species is a derived trait. Gene-based phylogenies have limited resolutions because DNA sequences are prone to homoplasy, introgression, and ancestral polymorphism. Therefore, they must be corroborated by an independent approach based on phylogenomics analysis of entire genomes. The rearrangement-based phylogeny reconstruction has been proven to be an effective and informative way to understand evolutionary relationships among various taxa (Bourque, Pevzner, Tesler 2004; Bhutkar, Gelbart, Smith 2007; Alekseyev, Pevzner 2009). Given the abundance and uniqueness of fixed inversions in the evolution of *Anopheles* (Sharakhova et al. 2010a; Xia et al. 2010), this approach should produce a reliable phylogenetic framework for comparative genomics studies of vectorial capacity (Xia, Sharakhova, Sharakhov 2008). The focus of this chapter is to review a role of chromosomal changes in adaptation and speciation of mosquitoes from the subgenus *Cellia*, which is the largest subgenus within the genus *Anopheles* and is restricted to the Old World. This subgenus includes some of the most important malaria vectors, such as *An. gambiae*, *An. nili*, *An. funestus*, and *An. stephensi*. The *An. gambiae* and *An. funestus* lineages diverged from a common ancestor at least 36 MY ago (Krzywinski, Grushko, Besansky 2006).

1. A ROLE OF CHROMOSOME POLYMORPHISM IN ECOLOGICAL ADAPTATIONS OF MALARIA MOSQUITOES

Data obtained on various organisms suggest that chromosomal polymorphism is a mechanism species use to rapidly adapt to climate changes. Environment-dependent changes in the frequencies of chromosomal inversions can be seen within a human lifetime (Krimbas, Powell 1992; Gordeev, Ejov 2004; Hoffmann, Daborn 2007). Development of “slash-and-burn” agricultural techniques allowed humans to leave the wet tropical forest and spread into dry areas in the tropics and sub-tropics (Coluzzi et al. 2002; Ayala, Coluzzi 2005). Likewise, adaptation to aridity was a key ecological adaptation that allowed malaria mosquitoes to occupy large regions and survive during dry seasons in Africa and Asia. What is the evidence for a role of chromosomal inversions in ecological adaptation of species? Several observations suggest that inversion polymorphism is likely the major mechanism by which malaria mosquitoes adapt to aridity. The polytene chromosome complement of *Anopheles* females consists of the X chromosome and four autosomal arms: 2R, 2L, 3R, and 3L. Of the seven members of the *An. gambiae* complex, *An. arabiensis* and *An. gambiae* s.s. are the only species that have a highly polymorphic chromosome 2 and a continent-wide distribution in arid sub-Saharan Africa. Mosquito species with little or no chromosomal polymorphisms tend to occupy smaller and wetter geographic regions (Coluzzi et al. 2002). However, the casual relationships between the level of polymorphism and the geographic distribution have not been tested experimentally. The 2Rb, 2Rbc, 2Rcu, 2Ru, 2Rd, and 2La inversions of *An. gambiae* are frequent in arid Sahel Savanna mosquitoes and almost absent in those in humid equatorial Africa, strongly suggesting that these inversions confer adaptive fitness to the drier environment (Coluzzi et al. 1979; Toure et al. 1998; Powell et al. 1999; Coluzzi et al. 2002). The nonrandom pattern of distribution of adaptive inversions suggests that these rearrangements are the product of selection. Natural selection has been implemented in fixation of the 2Rj inversion during ecotypic speciation in *An. gambiae* (Manoukis et al. 2008). Finally, the variations in rates of water loss and in thermotolerance are associated with alternative arrangements of the 2La inversion in *An. gambiae* (Gray et al. 2009; Rocca et al. 2009).

Anopheles gambiae is highly polymorphic for the two 2La arrangements, which are non-randomly distributed temporally and spatially with respect to degree of humidity in East and West Africa (Petrarca et al. 2000). This pattern is most apparent in West Africa (Coluzzi et al. 1979), where strong north-south clines in the frequency of the 2La inversion range from fixation in the arid northern Sahel to absence in the humid southern rainforests. At sites along the cline where neither arrangement is fixed, seasonal fluctuations occur in which 2La cycles from low to high frequency between wet and dry seasons. The adaptive flexibility provided by this chromosomal polymorphism has probably allowed *An. gambiae* to exploit a very broad range of climatic conditions, an important factor underlying the wide distribution and abundance of this species across Africa as well as its status as primary malaria vector. In addition, the inverted arrangements have been preferentially associated with indoor biting and resting behaviors (Coluzzi et al. 1979; Powell et al. 1999). Thus, chromosomal inversions could influence epidemiologically important traits of *An. gambiae*, such as its geographic distribution, its probability of vector-human contact, and the likelihood of vector exposure to insecticide-treated walls and bed nets.

Ecological adaptations have played a central role in the radiation of *An. gambiae*. It is believed that dry seasons and zones without artificial irrigation were the ecological limits to the spatial and temporal distribution of *An. gambiae* in the past. However, today, man-made modifications of the environment, such as large irrigation schemes, are perfectly exploited all year-round by a genetically distinct taxonomic unit of *An. gambiae sensu stricto* named the M form (Pombi 2005; Gimonneau et al. 2012). This adaptation represents a clear shift from breeding in natural, sunlit, temporary rain-dependent pools characteristic of the other taxonomic unit, the S form. These two forms were first described on the basis of the virtual absence of hybrid genotypes between form-specific haplotypes found in ribosomal DNA-linked markers (Gentile et al. 2001). The process of ecological divergence is probably driven by expansion of the original larval niche of the S form, which is considered to be ancestral (Lehmann, Diabate 2008; Costantini et al. 2009). However, sunlit, temporary, freshwater pools, such as road traces, are now created by human activity as well. The ecological factors and genetic mechanisms used by the M and S forms to partition their larval environment are not known. Differential oviposition behavior, possibly affected by the chemical composition of water, the ability of larvae to escape predators, and the availability of nutrients could be among the ecological factors (Edillo et al. 2006; Diabate et al. 2008; Gimonneau et al. 2010). A likely genetic mechanism of this ecological divergence is the capture and protection of adaptive allele combinations by chromosomal inversions, as suggested by studies on adult populations of *An. gambiae* (Manoukis et al. 2008; White et al. 2009).

2. ECOLOGICAL HETEROGENEITY OF MALARIA MOSQUITOES IS A MAJOR CHALLENGE TO VECTOR CONTROL

Malaria has a devastating impact on public health and welfare on the African continent and vector control is seen as a cornerstone of the malaria control strategy worldwide. Because of economic and practical reasons, vector control in Africa mainly relies on the use of synthetic insecticides (Takken, Knols 2009). However, this strategy is inefficient if all vector species and populations are not targeted and is further jeopardized by the rapid spread of insecticide multi-resistance in major mosquito vector species. The most efficient African malaria vector *An. gambiae* consists of populations that adapt to different environments, exhibit alternative behaviors, and vary in their vectorial capacity (Lehmann, Diabate 2008; Riehle et al. 2011). Some malaria control initiatives have been unsuccessful because they targeted the wrong species or population (Coluzzi 1992; Van Bortel et al. 2001). For example, the famous \$6-million Garki malaria control program in Nigeria failed because the massive indoor residual spraying of insecticides against *An. gambiae* did not impact the chromosomally distinct outdoor population (Coluzzi et al. 1977).

Malaria in tropical, humid savannah and forest environments is quite stable with entomological inoculation rates (EIR: number of infective bites per person per year) varying between 50 and 300 (Fontenille, Simard 2004). Five major vector species are responsible for malaria transmission in these areas: *An. gambiae*, *An. arabiensis*, *An. funestus*, *An. moucheti*, and *An. nili* (Fontenille, Simard 2004). These species are responsible for >95% of the total malaria transmission on the African continent (Mouchet et al. 2004). *Anopheles nili* has as wide a geographic distribution as *An. gambiae*, *An. arabiensis*, and *An. funestus*, spreading across

most of West, Central, and East Africa, mainly in humid savannah and degraded rainforest areas (Antonio-Nkondjio et al. 2009; Ayala et al. 2009). However, unlike other major vectors, *An. nili* breeds in slow-moving streams and large lotic rivers exposed to light and containing vegetation or debris (Fontenille, Simard 2004; Antonio-Nkondjio et al. 2009). A recent study of the ecological niche profile of major malaria vectors in Cameroon demonstrated that the habitats of *An. gambiae*, *An. arabiensis*, and *An. funestus* have more overlap with each other than with the habitats of *An. moucheti* and *An. nili* (Ayala et al. 2009). This results in a much more unusual geographic distribution of *An. moucheti* and *An. nili*, revealing their crucial role in malaria transmission in degraded and equatorial forests in Cameroon (Antonio-Nkondjio et al. 2009).

Key features that render *Anopheles* species very efficient malaria vectors are host-seeking and resting behavior, ecological adaptations, reproductive biology, longevity, and vector competence. Unique aspects of ecological adaptation and behavior of each malaria vector can, in part, explain the sustained malaria transmission in Africa (Table 1).

At least some of the epidemiologically important features are associated with inversion polymorphisms. For example, the 2La inversion in *An. gambiae* has been associated with a tolerance to aridity and reduced susceptibility to *Plasmodium falciparum* (Coluzzi et al. 1979; Petrarca, Beier 1992; Gray et al. 2009). The two major malaria vectors *An. arabiensis* and *An. gambiae* had been sympatric species in most of their distribution range, allowing for introgressive hybridization between them. Available data support the hypothesis of introgression of the 2La arrangement from *An. arabiensis* into *An. gambiae* (Besansky et al. 2003; White et al. 2009; Neafsey et al. 2010). The frequency of chromosomal inversion 2La is correlated with microclimatic differences in humidity that impact mosquito behavior: this arrangement is more common in mosquitoes found resting indoors where a nocturnal saturation deficit exists (Powell et al. 1999). Such population heterogeneity has important epidemiological and ecological consequences. Indoor residual spraying of insecticides against *An. gambiae* did not impact the population uniformly. It has major implications now because WHO is recommending the use of indoor residual spraying throughout Africa. Therefore, understanding and targeting the heterogeneity and complexity of *An. gambiae* is necessary for effective vector control and malaria elimination.

Table 1. Epidemiologically important adaptations and behaviors of four major malaria vectors in sub-Saharan Africa

	<i>An. gambiae</i>	<i>An. arabiensis</i>	<i>An. funestus</i>	<i>An. nili</i>
Preferential resting (Fontenille, Simard 2004)	Indoor	Indoor/ Outdoor	Indoor	Indoor/Outdoor
Preferential biting (Dia et al. 2003; Fontenille, Simard 2004; Antonio-Nkondjio et al. 2006)	Indoor	Indoor/ Outdoor	Indoor	Indoor/Outdoor
Biting time peak (Hanney 1960; Lemasson et al. 1997; Taye et al. 2006; Keraf-Hinzoumbe et al. 2009)	12 am – 5 am	11 pm – 5 am	11 pm – 6 am	10 pm – 1 am
Host preference (Lemasson et al. 1997; Dia et al. 2003; Antonio-Nkondjio et al. 2006)	Human	Human/ Animal	Human	Human/Animal
Peak of seasonal abundance (Lemasson et al. 1997; Antonio-Nkondjio et al. 2002; Dia et al. 2003; Keraf-Hinzoumbe et al. 2009)	July–October	July–October	October–November	October–December
Larval habitats (Fontenille, Simard 2004; Antonio-Nkondjio et al. 2009)	Rain- or irrigation-dependent pools	Grassy swamps		Lotic rivers, exposed to light

A chromosomal study of indoor-collected adult females in Burkina Faso found non-random spatial distribution of inversion variants with reference to environmental variables and habitat quality. The same karyotypes have been shown to be spatially distributed in a parallel pattern in both M and S molecular forms in response to gross environmental gradients of climate, vegetation, and land cover (Costantini et al. 2009). A likely reason for the lack of association between inversion polymorphisms and types of larval habitats in this study is that indoor-resting adult females represent only a fraction of the natural population of *An. gambiae*. Indeed, a recent study of larval genotypes in the Goundry village of Burkina Faso discovered an unexpected genetic diversity within *An. gambiae* (Riehle et al. 2011). The study suggests the presence of a previously unidentified genetically distinct subgroup of *An. gambiae*. The new form is presumably exophilic and abundant, lacks differentiation into M and S molecular form genetic markers, and is highly susceptible to infection with wild *Plasmodium falciparum*. Interestingly, 2La inversion alleles are significantly different in the larval pool (where the 2L⁺ arrangement occurs at a frequency of 68%) and the indoor-resting mosquito collections, which are nearly fixed for the inverted 2La allele (98%). Thus, indoor captures likely provide a biased description and estimate of *An. gambiae* genetic diversity. However, collecting adult mosquitoes outdoors is notoriously difficult because of the lack of effective sampling methods and ethical problems with using humans as bait. Aquatic larvae are relatively easier to collect, and they are more likely to represent the full genetic diversity of the species. Detailed chromosomal analyses of larval populations may reveal new rare inversions or combinations thereof that are not represented in indoor adult populations. In addition, these unprecedented investigations may reveal new functions of the common aridity-linked ‘adult’ chromosomal arrangements 2Rb, 2Rc, 2Ru, 2Rd, and 2La at the larval stage, at which a mosquito grows and spends a significant portion of its active lifetime.

If niche partitioning is associated with specific polymorphic inversions, as is postulated with indirect evidence from adult sampling (Toure et al. 1994), then the higher diversity of available types of water reservoirs will contribute to the higher genetic diversity of the adult population. Detailed knowledge of the extent of chromosomal complexity and heterogeneity of *An. gambiae* populations will, thus, be useful for vector control. A possible introgression of inversion arrangements could impact the dynamics of mosquito adaptation and malaria transmission. Therefore, understanding the association between inversion polymorphism and ecological adaptations may lead to identification of phenotype-causing alleles that could be targeted in the future.

3. CHROMOSOME PLASTICITY IN ADAPTATION AND EVOLUTION OF MALARIA MOSQUITOES

A growing number of studies suggest that chromosome rearrangements play an important role in species evolution and adaptation (Noor et al. 2001; Rieseberg 2001; Feder et al. 2003; Schaeffer et al. 2003; Anderson et al. 2005; Ayala, Coluzzi 2005; Kirkpatrick, Barton 2006; Baack, Rieseberg 2007; Hoffmann, Daborn 2007; Noor et al. 2007; Manoukis et al. 2008). An intriguing fact is that the rates of rearrangements are taxon and chromosome sensitive (Gonzalez, Ranz, Ruiz 2002; Sharakhov et al. 2002; Coghlan et al. 2005; Ranz et al. 2007). Comparison of vertebrate genomes demonstrated a slow rate of chromosomal evolution in fish

and chicken and an accelerated rate of genome rearrangements in mammals (Postlethwait et al. 2000; 2004). Within mammals, rodent lineages have undergone 3.2–3.5 chromosome rearrangements per million years (MY) while primates have accumulated only 1.6 rearrangements per MY since the two lineages diverged. Within carnivores, the rate of chromosome evolution in *Canidae* is much higher than in other lineages (Yang et al. 1999). Comparison of genomic sequences of 12 species of *Drosophila* revealed that inversions have been fixed at different rates in different lineages (Clark et al. 2007). For example, 29 fixed inversions are located between *D. melanogaster* and *D. yakuba*. All but one of these inversions occurred in the *D. yakuba* lineage (Ranz et al. 2007). Likewise, the distribution of polymorphic rearrangements varies dramatically among lineages. More than 500 polymorphic inversions are known for *D. melanogaster* while only 14 inversions have been described for its close relative, *D. simulans* (Aulard et al. 2004a). Cytogenetic studies performed on malaria mosquitoes provided some of the most obvious examples of the nonuniform inversion distribution both among species and chromosomal arms (Coluzzi et al. 2002; Sharakhov et al. 2002; Pombi et al. 2008; Xia et al. 2010). The availability of the *An. gambiae* genome sequence (Holt et al. 2002) and the physical maps for *An. funestus* (Sharakhov et al. 2002; Sharakhov et al. 2004) and *An. stephensi* (Xia et al. 2010) enabled a fresh perspective to be gained on the relationships between the genomic landscape and evolutionary rates. Taxonomically, these species belong to the different series of the subgenus *Cellia* diverged: *Pyretophorus* (*An. gambiae*), *Myzomyia* (*An. funestus*), and *Neocellia* (*An. stephensi*) (Green, Hunt 1980). Comparative mapping between *An. gambiae* and *An. funestus* established arm homologies among these species, found no evidence for inter-arm transposition events, pericentric inversions, or partial-arm translocations, and confirmed that whole-arm translocations and paracentric inversions are the common rearrangements among species in subgenus *Cellia* (Green, Hunt 1980; Sharakhov et al. 2002) (Xia et al. 2010). Given that *An. gambiae* and *An. funestus* diverged from each other at least 36 million years ago (Krzywinski, Grushko, Besansky 2006), the rate of genome rearrangement in the subgenus *Cellia* is 0.003-0.005 inversions per 1 megabase (Mb) per million years per lineage.

3.1. Chromosome Arms Evolve at Different Rates

The availability of polytene chromosomes in anopheline mosquitoes allows for the development of comparative maps that can be used to determine sizes of syntenic regions. A recent study mapped 231 uniquely located markers to the *An. stephensi* chromosomes for a comparative study with *An. gambiae* and *An. funestus* (Xia et al. 2010). The number of inversions between *An. gambiae* and *An. stephensi* using the Nadeau and Taylor method (Nadeau, Taylor 1984) and the Genome Rearrangements In Man and Mouse (GRIMM) program (Tesler 2002) has been calculated. Both Nadeau-Taylor and GRIMM analyses revealed of inversion that the X chromosome had the highest rate fixation and that the 2R arm evolved faster than other autosomes (Xia et al. 2010) (Figure 2). Another study demonstrated a striking contrast among chromosome arms in the length of conserved segments: small conserved blocks (< 1 Mb) are located on arm 2R, and large conserved blocks (up to 6-8 Mb) are located on arms 3R and 3L (Sharakhova et al. 2011).

Of 10 inversions fixed among species of the *An. gambiae* complex, 5 have been found on the X chromosome and 3 on the 2R arm (Coluzzi et al. 2002). In contrast to the polymorphic

inversions, the majority of species-specific inversions (5 of 10) were found on the X (sex) chromosome in the *An. gambiae* complex (Coluzzi et al. 2002). The contrasting pattern of inversion polymorphism and inversion fixation on the X chromosome suggests that different forces govern sex chromosome and autosome evolution. The excess of fixed inversions and the deficit of polymorphic inversions on the X chromosome has been explained by the underdominance (homozygote advantage) model of speciation (Charlesworth, Coyne, Barton 1987). It has been proposed that genes responsible for species reproductive isolation could be located on the X chromosome (Ayala, Coluzzi 2005). Indeed, the X chromosome has a disproportionately large effect on male and female hybrid sterility in *An. gambiae* and *An. arabiensis* (Slotman, Della Torre, Powell 2004; Slotman, Della Torre, Powell 2005). The smaller effective population size of the X chromosome, as compared to autosomes, suggests that drift might have played a bigger role in the rapid fixation of the inversion on the X chromosome. The rapid evolution of sterility and inviability genes captured by polymorphic inversions on the X chromosome may cause a selection against inversion heterozygotes. From a vector control point of view, if heterozygote inversions on the X chromosome have a deleterious effect on viability and reproduction of mosquitoes, then they could be introduced artificially into the vector population to reduce its size. A study of gene ontology (GO) term distribution suggests that the X chromosome is enriched in genes that may be involved in premating isolation, such as genes encoding for proteins with molecular and signal transduction activity. Signal transduction is a crucial component of olfaction that plays a major role in mate recognition. For example, X-linked genes encoding for signal transduction proteins were differentially expressed between virgin females of two incipient species of *An. gambiae* that differ in swarming behavior (Cassone et al. 2008). Rapid generation and fixation of inversions on the X chromosome may facilitate speciation in *Anopheles* by differentiating alleles inside of the inverted regions as has been shown in *Drosophila* (Machado, Haselkorn, Noor 2007). Unlike the X chromosome in insects, the eutherian X chromosome had its gene order conserved during 105 million years of evolution, probably reflecting strong selective constraints posed by the X inactivation system in mammals (Rodriguez Delgado et al. 2009).

A study of the opossum genome revealed that the evolution of the X chromosome inactivation was associated with suppression of large-scale rearrangements in eutherians (Mikkelsen et al. 2007). Conversely, rapidly evolving sex chromosomes in insects have a dosage compensation system. Because the X chromosome in *Drosophila* males recruits fewer histones and possesses an “open” chromatin (Corona et al. 2007), it may be more sensitive to breakage (Fisher et al. 2005) and, thus, more prone to rearrangements.

In contrast to the X chromosome, the 2R and 2L arms of *An. gambiae* and their homologous arms in *An. stephensi* and *An. funestus* harbor polymorphic inversions associated with ecological adaptations (Mahmood, Sakai 1984; Costantini et al. 1999; Coluzzi et al. 2002). Natural selection has been implicated in fixation of the 2Rj inversion during ecotypic speciation in *An. gambiae* (Manoukis et al. 2008). Adaptive alleles or allelic combinations can be maintained within a polymorphic inversion by suppressing recombination between the loci (Kirkpatrick, Barton 2006; Hoffmann, Rieseberg 2008). It has been demonstrated that adaptive inversions are less frequent at shorter lengths (Caceres, Barbadilla, Ruiz 1997; Pombi et al. 2008), reflecting a smaller selective advantage when an inversion captures fewer genes (Krimbas, Powell 1992). Therefore, it has been predicted that chromosomal arms rich in polymorphic inversions (2R, 2L) would have higher gene densities. This prediction was met; moreover, the polymorphic inversion-poor X chromosome had the lowest gene density (Xia et

al. 2010). Similarly, the polymorphic inversion-rich chromosomal elements C and E have higher gene densities than the rest of the genome in *Drosophila* (Gonzalez, Ranz, Ruiz 2002). These observations highlight the fundamental differences between the evolutionary dynamics of the sex chromosome and autosomes. The high rate of sex chromosome evolution is being achieved by the rapid generation and fixation of inversions without maintenance of a stable inversion polymorphism. In contrast, the high rate of the autosomal evolution results from the high level of inversion polymorphism maintained by selection acting on gene-rich chromosomal arms. The increase of gene density in rearrangement-rich regions of autosomes was also found in vertebrates (Murphy et al. 2005; Gordon et al. 2007; Larkin et al. 2009) suggesting the general applicability of the principle “from polymorphism to fixation” to autosomal evolution.

Figure 2. The gene order transformation between *An. gambiae* and *An. stephensi*. Relative position and orientation of the conserved syntenic blocks are shown by blocks. Numbers within the blocks indicate markers physically mapped to polytene chromosomes. Numbers over brackets show inversion steps. The telomere ends are on the left (Xia et al. 2010).

The polymorphic inversions 2Rb, 2Rbc, 2Rcu, 2Ru, 2Rd, and 2La of *An. gambiae* are associated with adaptation of mosquitoes to the dry environment (Coluzzi et al. 2002). Cuticle seems to play a major role in desiccation resistance of embryo and adult mosquitoes (Goltsev et al. 2009; Gray et al. 2009). These observations suggest an exciting possibility that genes involved in the cuticle development may be disproportionally clustered on the 2R and 2L arms. A study of GO terms provides evidence that 2L is indeed enriched with genes involved in the structural integrity of a cuticle while the 2R arm has overrepresentation of genes involved in cellular response to stress (e.g., temperature, humidity) and in building membrane parts (Xia et al. 2010). These data support the role of natural selection in maintaining polymorphic inversions associated with ecological adaptations.

3.2. Genomic Landscapes and Nonuniform Rates of Inversions Fixation

Evolution of gene order likely has species- and chromosome-specific facilitators or inhibitors. The major consequences of unequal rates of karyotype evolution are differential plasticity of species and an increased role of certain chromosomes in adaptation and evolution (Coluzzi et al. 2002; Hoffmann, Sgro, Weeks 2004). What are the factors that constrain or promote chromosomal rearrangements? The common assumption about the major role of transposable elements (TEs) in generating inversions (Caceres et al. 1999; Mathiopoulos et al. 1999; Evgen'ev et al. 2000) was not supported by other studies (Matzkin et al. 2005; Richards et al. 2005; Ranz et al. 2007). Moreover, the TE density in the *An. gambiae* genome was found to be lowest on the 2R arm (Holt et al. 2002); thus, it is not clear whether the molecular content could be associated with inversion polymorphism and fixation rates. A recent study has shown that fragility of certain regions rather than functional constraints plays the main role in nonuniform distribution of inversions in *Drosophila* chromosomes (von Grotthuss, Ashburner, Ranz 2010). However, the molecular determinants of the fragile breakage have not yet been determined. If nonrandom origin of inversions can be attributed to unequal density of repetitive DNA among chromosome arms, higher densities of break-causing elements on faster evolving arms can be predicted.

A study of the distribution of 82 rare polymorphic inversions in *An. gambiae* s.s. has found no inversions on the X chromosome, 67 inversions on the 2R arm, and only 15 inversions on the 2L, 3R, and 3L arms together (Pombi et al. 2008) (Figure 3). The clustering of neutral chromosomal polymorphisms and cytological co-localization of multiple breakpoints on 2R indicates that this arm is especially prone to breakages (Coluzzi et al. 2002; Pombi et al. 2008). The high rate of rearrangements could be explained by 2R-biased distribution of repetitive DNA capable of generating inversions. However, the transposable element density in the *An. gambiae* genome was found to be lowest on the 2R arm (Holt et al. 2002) (Xia et al. 2010) and, thus, it is not clear whether the molecular content could be associated with inversion fixation rates. Although, the role of transposable elements in the origin of individual inversions was demonstrated earlier (Mathiopoulos et al. 1998; Caceres et al. 1999), their presence at the breakpoints has not been confirmed by genome-wide analyses in *Drosophila* (Richards et al. 2005; Ranz et al. 2007; Bhutkar et al. 2008). Segmental duplications have been found in the opposite orientation at the breakpoints of the 2Rj inversion of *An. gambiae* and have been implicated in generating this rearrangement (Coulibaly et al. 2007). Simple repeats have been shown to play a role in the formation of hairpin and cruciform structures, which can cause

double-strand DNA breaks and rearrangements (Lobachev, Rattray, Narayanan 2007). In *Drosophila*, the microsatellite density of the chromosomes parallels their evolution rates (Gonzalez, Ranz, Ruiz 2002).

Figure 3. Distribution of polymorphic inversions among chromosomal arms X, 2R, 2L, 3R, and 3L in *An. gambiae*. Brackets above chromosomes indicate rare polymorphic inversions, and brackets below chromosomes show common polymorphic inversions (Pombi et al. 2008).

A recent study applied a Bayesian statistical model and procedure for discerning differences between arms in molecular features, such as DNA-mediated TEs (DNA TEs), RNA-mediated TEs (RNA TEs), segmental duplications (SDs), micro- and minisatellites, satellites, MARs, and genes (Xia et al. 2010) (Figure 4). The X chromosome had the highest density of TEs and the highest coverage of microsatellites, minisatellites, and satellites. The 2R arm had the highest density of genes and regions involved in SDs but had the lowest densities of TEs and the lowest coverage of minisatellites and MARs. This study detected the highest density of regions with SDs in the proximal half of the 2R arm where the breakpoint-rich area is located (Pombi et al. 2008) (Figure 3). The correlation coefficient between the densities of breakpoints and regions involved in SDs in 5-Mb intervals within 50 Mb of the euchromatic part of 2R was 0.9, suggesting an arm-specific involvement of SDs in inversion formation rather than a genome-wide impact.

Simple repeats have been shown to play a role in the formation of hairpin and cruciform structures, which can cause double-strand DNA breaks and rearrangements (Lobachev, Rattray, Narayanan 2007). In *Drosophila*, the fastest evolving X chromosome has the highest densities of microsatellites and TEs (Gonzalez, Ranz, Ruiz 2002; Fontanillas, Hartl, Reuter 2007). Although, the role of TEs in the origin of individual inversions was demonstrated earlier (Lyttle, Haymer 1992; Mathiopoulos et al. 1998; Caceres et al. 1999; Mathiopoulos et al. 1999; Aulard et al. 2004b), the more recent sequencing of breakpoints discovered alternative mechanisms of inversion generation (Richards et al. 2005; Sharakhov et al. 2006; Ranz et al. 2007; Bhutkar et al. 2008). SDs have been implicated in inversion generation in mosquitoes and mammals (Goidts et al. 2004; Coulibaly et al. 2007) and are considered as a marker of genome fragility (Bailey et al. 2004).

Figure 4. Genome landscapes of the *An. gambiae* chromosomal arms. Median counts per 1 Mb are given for regions involved in SDs (Xia et al. 2010). The coordinates and orientation of each arm are the following: X: 0 Mb—telomere, 24.3 Mb—centromere; 2R: 0 Mb—telomere, 61.5 Mb—centromere; 2L: 0—centromere, 50 Mb—telomere; 3R: 0 Mb—telomere, 53.2 Mb—centromere; 3L: 0 Mb—centromere, 41.9 Mb—telomere.

The *An. gambiae* X chromosome and 2R arm have the highest G+C content. GC-rich regions have been implemented in forming hotspots for chromosome rearrangements (Fisher et al. 2005; Gordon et al. 2007) because of their propensity to form Z-DNA, hairpin loops, and other unstable structures that are capable of generating double-strand breaks (Wang, Christensen, Vasquez 2006). Interestingly, a GO term analysis demonstrated that the X

chromosome is enriched with nucleobase, nucleoside, and nucleotide metabolic processes and that the 2R arm has overrepresented gene clusters involved in DNA damage repair. It is possible that these GO term enrichments have evolved in response to high rates of DNA breakage on the X and 2R chromosomes. Because of the paucity of pericentric inversions and partial-arm translocations in mosquito evolution, the genome landscapes and evolutionary histories of individual arms are different. There is a strong association between the genome landscape characteristics and the rates of chromosomal evolution. A unique combination of various classes of genes and repetitive DNA in each arm, rather than a single type of repetitive element, is likely responsible for arm-specific rates of rearrangements. These findings call for a reevaluation of the genomic analyses, which must be performed on an arm-by-arm basis using sequences physically mapped to the chromosomes.

3.3. Polymorphic Inversions and Parallel Adaptations

As was mentioned previously, polymorphic chromosomal inversions are highly non-uniformly distributed among five chromosomal arms of malaria mosquitoes. In *An. gambiae* s.l., 18 of the 31 common polymorphic inversions (58%) are on chromosome 2R, which represents less than 30% of the polytene complement. Of the eight common polymorphic inversions described in *An. gambiae* s.s., seven occur on chromosome 2R and one on chromosome 2L (Coluzzi et al. 2002). The central part of chromosomal arm 2R appears to play a major role in both chromosomal changes between species and in the polymorphism within species of the *An. gambiae* complex. Similarly, in distantly related malaria vectors, *An. gambiae* s.s., *An. funestus*, and *An. stephensi*, the majority of successful polymorphic inversions are located on chromosomal arm 2R (Mahmood, Sakai 1984; Coluzzi et al. 2002; Sharakhov et al. 2004). Is the concentration of adaptive rearrangements on just one of five chromosomal arms in the distant mosquito species coincidental or does it reflect a common genetic mechanism of adaptation to a dry climate? The location of ecologically important inversions on chromosome arm 2R in different species may reflect the importance of specific (homologous) genomic regions in the evolution and adaptation of mosquitoes. If the phenotype associated with inversion polymorphisms is the same in *An. gambiae*, *An. funestus*, and *An. stephensi*, the common genes, gene families, and clusters are likely to be responsible for the ecological adaptation of these species. Natural selection seems to play a role in maintaining inversion polymorphisms on 2R and 2L of *An. gambiae* and their homologous arms in *An. stephensi* and *An. funestus* (Mahmood, Sakai 1984; Costantini et al. 1999; Coluzzi et al. 2002).

A previous study has shown that chromosomal arms rich in polymorphic inversions (2R, 2L) have higher gene densities (Xia et al. 2010). This observation confirmed the assumption that an inversion with fewer genes would have a smaller selective advantage (Krimbas, Powell 1992). Moreover, the study of gene ontology terms has provided evidence that 2L is enriched with genes involved in the structural integrity of a cuticle, while the 2R arm has an overrepresentation of genes involved in cellular response to stress (e.g., temperature, humidity) (Xia et al. 2010). These data strongly support the role of natural selection in maintaining polymorphic inversions associated with adaptation of mosquitoes to the dry environment (Coluzzi et al. 2002). A study of larval ecology demonstrated that sympatric species *An. gambiae* and *An. funestus* inhabit a wide range of the same ecological settings in Cameroon (Ayala et al. 2009). If polymorphic inversions in the distant species confer the same adaptations

then similar sets of genes can be present within inversions of these species. The presence of similar sets of genes within independent inversions would imply the role of natural selection acting on similar genetic content of homologous chromosomal arms and creating parallel phenotypes of the evolutionary distant species. A theoretical model suggests that the probability of parallel evolution under natural selection is about two times bigger than that under neutrality (Orr 2005). Results of a recent study demonstrated that inversions on 2L of *An. gambiae*, 3L of *An. stephensi*, and 3R of *An. funestus* have almost random sets of genes (Sharakhova et al. 2011). This study found that the several 2R inversions in *An. gambiae*, *An. stephensi*, and *An. funestus* do share common genes. The 2Rf inversion of *An. stephensi* has an increased frequency in the urban environment (Mahmood, Sakai 1984) and nonrandomly share common genes with overlapping inversions 2Rc, 2Rd, 2Rbk, and 2Ru of *An. gambiae*. Another “urban” inversion in *An. stephensi*, 2Rb, had a gene homology to the inversion 2Rc of *An. gambiae*. In contrast, the 2Re inversion of *An. stephensi* has an increased frequency in the rural environment (Mahmood, Sakai 1984) and nonrandomly shares common genes with inversion 2Rb of *An. gambiae* and overlapping inversions 2Rd/2Rh of *An. funestus*. This nonrandom distribution of markers is not only the result of preservation of ancestral gene order. In fact, cases with extensively reshuffled gene orders have been found within independently originated polymorphic inversions.

The gene shuffling is common in malaria mosquitoes (Xia et al. 2010), and these species are phylogenetically distant enough from each other (Green, Hunt 1980; Krzywinski, Grushko, Besansky 2006) to have independently originated polymorphic inversions, which differ in chromosomal positions and size. The nonrandom presence of homologous genes within inversion 2Rb of *An. gambiae* and inversion 2Rh of *An. funestus* is especially interesting in the light of ecological adaptations associated with these inversions. The high frequency of the 2Rb inversion of *An. gambiae* has been found strongly associated with increased degree of aridity. In contrast, the low frequencies of this inversion have been recorded in humid areas (Coluzzi et al. 1979). The 2Rh inversion of *An. funestus* has a similar (although reverse) pattern of association with aridity. Correlation of the 2Rh inversion with the higher vapor pressure has been demonstrated the strongest among all studied inversions of *An. funestus*. In contrast, the standard (2Rh+) arrangement has been found associated with the lower vapor pressure (Ayala et al. 2011). Thus, it is likely that natural selection favors adaptive gene combinations within polymorphic inversions on 2R when distantly related species are exposed to similar environmental pressures. The availability of these gene complexes would support long-term maintenance of polymorphic inversions. This knowledge could be useful for the discovery of genes responsible for an association of inversion polymorphisms with phenotypic variations in multiple species. If candidate genes were identified within a polymorphic inversion in one species, the orthologous genes in another species likely play a similar role in adaptation if they are captured by a polymorphic inversion involved in the parallel adaptation. Future studies should identify specific alleles associated with parallel adaptation of species of subgenus *Cellia*.

3.4. Nuclear Architecture and Chromosome Plasticity

Polymorphic inversions tend to cluster on the chromosomal arms 2R and 2L but not on X, 3R and 3L in *An. gambiae* and homologous arms in other species. However, it is unclear if the evolutionary breakage of inversion-poor chromosomal arms is under constraints. A recent study

has detected the chromosomal arm specificity in rates of gene order disruption during mosquito evolution (Sharakhova et al. 2011). It concluded that the distribution of breakpoint regions is evolutionary conserved on slowly evolving arms and tends to be lineage-specific on rapidly evolving arms. It has been hypothesized that the arm-specific tolerance to chromosomal breakage could be responsible for the nonuniform distribution of inversions in autosomes. The comparative analysis of conserved and disrupted gene blocks in chromosomal arms across the three species provided evidence that 2R is more tolerant to disrupting gene orders and generating new evolutionary breakpoints than other arms. The study observed that if a block on 2R was conserved between two mosquito species it was likely disrupted in the third species. In contrast, all identified gene blocks remain preserved on the 3R arm of *An. gambiae* and the homologous arms of the other species suggesting the existence of arm-specific constraints to breakage. These constraints could be controlled by negative selection acting against disruption of certain gene combinations. It is possible that slowly and rapidly evolving chromosomes may differ in sizes or abundance of coregulated gene clusters. Accumulating evidence suggests that gene order in eukaryotic genomes randomly aggregates in clusters with similar expression levels (Michalak 2008). Purifying selection against genomic rearrangements may preserve physical colocalization of coexpression clusters (Hurst, Pal, Lercher 2004). For example, clusters of genes deregulated in *trx* mutant *D. melanogaster* larvae are not uniformly distributed along the genome; 60% of them are located on chromosome 3L (Blanco et al. 2008), which is a slowly-evolving arm in *Drosophila* (Ranz et al. 2007; Bhutkar et al. 2008). Physically clustered genes may have shared regulatory regions, common expression pattern, and chromatin-level regulation, or they may represent clusters of essential genes (Ng, Wu, Zhang 2009). Additionally, conservation of gene order in certain regions of the genome has been explained by long-range gene regulation (Mongin, Dewar, Blanchette 2009). If the 3R arm of *An. gambiae* is enriched in large functional gene clusters, then generating inversions on this arm or inserting a transgene into 3R will likely have a negative effect on mosquito fitness. Alternatively, the location of breakpoint clusters in only specific chromosomal regions of the 3R arm of *An. gambiae* and the homologous arms of the other species could be responsible for the preservation of the gene order in evolution. Indeed, a recent study has shown that fragility of certain regions rather than functional constraints plays the main role in nonuniform distribution of inversions in *Drosophila* chromosomes (von Grotthuss, Ashburner, Ranz 2010). If this is the case in mosquitoes, then the distribution of breakpoints is lineage-specific on 2R and evolutionary conserved on the 3R arm of *An. gambiae* and the homologous arms of the other species. A previous study has found that the 2R arm has the highest density of regions involved in segmental duplications that clustered in the breakpoint-rich zone of the arm. Future analyses of the genome sequence in different species will shed light on the exact mechanism of breakage in each individual chromosomal arm. Regardless of the mechanism, it is clear that new rearrangement breaks are more easily allowable on 2R than on other arms in different mosquito lineages, thus, contributing to the arm-specific differences in rates of chromosomal evolution in *Anopheles*.

An interesting observation is that specific genome rearrangements are often associated with the genesis of certain types of tumors in humans (Therman, Susman, Denniston 1989; Kozubek et al. 1999; Neves et al. 1999; Marshall 2002; Bartova et al. 2005; Gandhi et al. 2006; Folle 2008). Analyses of the architecture of these nuclei revealed a general principle: because of nonrandom nuclear organization, certain loci are nonrandomly close together in the nucleus and have increased opportunities to interact and generate rearrangements. A recent study of 3D

organization of the yeast genome revealed that interchromosomal contacts colocalize with fragile sites where chromosomal breakpoints occur in evolution (Duan et al. 2010). Additionally, other interactions may be inhibitory. Matrix-associated regions (MARs) of DNA can bind directly to lamin—a major protein of the nuclear envelope—and can potentially increase chromosome stability in the cell nucleus (Baricheva et al. 1996; Dechat et al. 2008). Can evolutionary changes in nuclear architecture explain the taxon and chromosome specificity in rates of rearrangements? As demonstrated in insects, spatial organization of polytene chromosomes has species-specific characteristics. Closely related species within the *An. maculipennis* complex and the *D. melanogaster* subgroup can be discriminated on the basis of the spatial localization and morphology of the chromosomal regions to which the nuclear envelope is attached in germ-line cells (Stegnii 1987; Stegnii, Vasserlauf 1994). F1 hybrids between members of the *An. gambiae* complex demonstrate spatial separation of homologous polytene chromosomes in nuclear envelope-attachment regions suggesting reorganization of nuclear architecture during speciation (Coluzzi, Sabatini 1969). Although positioning within the nucleus of particular chromosomes is evolutionarily preserved between humans and higher primates (Tanabe et al. 2002; Neusser et al. 2007), mouse chromosomes are positioned at different nuclear locations within mouse nuclei when compared to the nuclear position of human chromosomes (Foster, Bridger 2005; Meaburn, Parris, Bridger 2005). Moreover, parental genomes are spatially separated in F1 hybrids between different species of mice (Mayer, Fundele, Haaf 2000; Mayer et al. 2000). Thus, drastic reorganization of nuclear architecture may occur during evolution. Comprehensive research efforts should specifically target nuclear architecture dynamics in evolution and its role in genome rearrangements.

Figure 5. A model of interaction of the 2R and 3L arms with the nuclear envelope (Xia et al. 2010).

To better understand the evolutionary dynamics of chromosomal inversions, a genomic study developed and deployed novel Bayesian statistical models to analyze genome landscapes in individual chromosomal arms *An. gambiae* (Xia et al. 2010). This study has shown that, unlike all other repeats, MARs were concentrated in arms 2L, 3R, and 3L (Figure 4). The study found a negative correlation between the rates of fixed inversions and MARs coverage ($r = -0.766$), suggesting a role for nuclear architecture in controlling the rearrangements. It has been proposed that multiple attachments of 2L, 3R, and 3L to the nuclear envelope make rejoining

different breaks and forming inversions more difficult despite the abundance of TEs and simple repeats in these arms. In contrast, the lower coverage of MARs on 2R makes fewer nuclear envelope—chromosome contacts and allows more interaction between loci (Xia et al. 2010) (Figure 5).

In the nuclei of most cell types and organisms, heterochromatin contacts with the periphery and plays an important role in maintaining spatial and functional organization of chromosomes (Joffe, Leonhardt, Solovei 2010). Pericentric heterochromatin of polytene chromosomes in fruit flies and mosquitoes is represented by two morphological types—compact and diffuse (Heitz 1934; Gall, Cohen, Polan 1971; Zhimulev 1998; Sharakhova et al. 2000; Sharakhov et al. 2001). A number of studies have demonstrated direct associations between diffuse but not compact heterochromatin and the nuclear envelope in fruit flies and mosquitoes (Hochstrasser, Sedat 1987b; Hochstrasser, Sedat 1987a; Baricheva et al. 1996; Sharakhov et al. 2001; Singh, Georgatos 2002; Akhtar, Gasser 2007; Scherthan 2007). It is possible that the compact and diffuse types of heterochromatin, because of their distinct molecular compositions, have different functions in the nucleus. Specialized nuclear envelope-associated chromosomal regions have been described in *Drosophila*, human, and mouse (Pickersgill et al. 2006; Guelen et al. 2008; Peric-Hupkes et al. 2010). They represent large genomic regions (from 40 kb to 15 Mb) that tend to reside in close (<50 nm) proximity to the nuclear envelope. However, the actual DNA sequence motifs responsible for these associations have yet to be discovered.

4. HETEROCHROMATIN AND SPECIATION IN MALARIA MOSQUITOES

It is now widely recognized that the functional characterization of any genome, in order to be meaningful, must include an understanding of the epigenome. One major focus of epigenomics is to study heterochromatin and the chromosomal proteins and histone modifications involved in DNA replication, gene expression, gene silencing, and inheritance. Epigenetic modifications are being extensively characterized in genomes of model organisms (<http://www.modencode.org>), humans (www.epigenome.org), and *Plasmodium* (Salcedo-Amaya et al. 2009; Ponts et al. 2010). *Anopheles* is the only member of the “malaria triad” that lacks epigenomic studies. The mosquito heterochromatin contains protein-coding genes and accumulates essential genes important for establishing, maintaining, and modifying chromatin structure (Grushko et al. 2009; Sharakhova et al. 2010b). The chromatin state largely determines the position of a locus with respect to the transcriptionally active nuclear interior and the nuclear periphery, which is a repressive environment with respect to transcription (Pickersgill et al. 2006; Fillion et al. 2010). The packaging of DNA into euchromatin and heterochromatin of *An. gambiae* could have major implications for understanding how genome sequences function and respond to *Plasmodium* infection. A recent study has shown that gene loci that are upregulated after infection with *Schistosoma* have become spatially repositioned in the nuclei of the infected cells of *Biomphalaria glabrata* snail into a significantly more interior location (Knight et al. 2011). The mechanism through which chromatin behavior and dynamics respond to parasitic infection could be a target to control infection. Therefore, characterization of heterochromatin domains will open a new venue for studying the *Anopheles*—*Plasmodium* interaction.

To determine the extent of heterochromatin within the *An. gambiae* genome, genes were physically mapped to the euchromatin-heterochromatin transition zone of polytene chromosomes. The study revealed that a minimum of 232 genes reside in 16.6 Mb of mapped heterochromatin (Sharakhova et al. 2010b). Gene ontology analysis revealed that heterochromatin is enriched in genes with DNA-binding and regulatory activities. Sequencing of the genome of the major African malaria vector *An. gambiae* (Holt et al. 2002) provides an opportunity to analyze the molecular structure of the heterochromatin and to study genomic determinants of heterochromatin formation, maintenance, and function. In malaria mosquitoes, the heterochromatin size and morphology of sex chromosomes vary significantly among species and within species (Gatti et al. 1977; Sharakhova, Stegnii, Braginets 1997; Sharakhova, Stegnii, Timofeeva 1997), possibly affecting mating behavior and fertility (Bonaccorsi et al. 1980). A genome-wide microsatellite study of members of the *An. gambiae* complex has determined a high level of genetic introgression among species (Wang-Sattler et al. 2007). However, the *An. gambiae* microsatellites at six loci of X, 3L, and 3R could not be amplified in all sibling species, indicating significant sequence divergence from the major malaria vector. These loci were identified as heterochromatic in another study (Sharakhova et al. 2010b).

In the *An. gambiae* complex, one of the species, *An. gambiae sensu stricto*, is subdivided into two subtaxa: the M and S molecular forms (della Torre et al. 1997). These two partially isolated subtaxa predominantly breed within their own form and differ in behavior and environmental adaptations (Lehmann, Diabate 2008). Earlier cytological studies showed the presence of significant intra- and interspecific differences in amount and location of heterochromatin in the *An. gambiae* complex (Gatti et al. 1977; Bonaccorsi et al. 1980). The major regions of genomic differentiation between M and S forms of *An. gambiae* have been found in pericentric regions of all chromosomes (White et al. 2010). The study found three islands of genomic divergence: a ~4-Mb region on the X chromosome, a ~2.5-Mb region on the 2L arm, and a 1.7-Mb region on the 3L arm. However, it is not clear if the pericentric islands of genomic divergence are located within heterochromatin or mostly overlap with euchromatin of *An. gambiae*. A recent analysis showed that the positions of islands of genomic divergence mostly correspond to the positions of physically mapped regions of pericentric heterochromatin (Sharakhova et al. 2010b) (Figure 6). The sizes of the pericentric heterochromatin were the following: 4.4 Mb of the X chromosome, 2.4 Mb of the 2L arm, and 1.8 Mb of the 3L arm. Thus, the overlaps with islands of genomic divergence are 91% in the X chromosome, 97% in the 2L arm, and 94% in the 3L arm. The high levels of genomic divergence in pericentric heterochromatin could be due to low recombination or selection or a combination of both factors. Although, more recent whole-genome sequencing showed the genome-wide pattern of divergence between the two forms, the pericentric heterochromatin of X and 2L as well as intercalary heterochromatin of 3R were among the highly diverged regions between the M and S forms (Lawniczak et al. 2010). Moreover, the pericentric heterochromatin of all three chromosomes exhibited the strongest signals of selective sweeps for the M and S forms, suggesting that the extensive divergence observed in these regions has been driven by selection (Neafsey et al. 2010). Of 536 genes experienced strong and recent selective sweep 161 genes are heterochromatic (9.7 gene per Mb), 153 genes are in pericentric heterochromatin (12.6 gene/Mb) and 375 genes are euchromatic (1.5 gene/Mb). It has been argued that variation in divergence between M and S forms across the genome is maintained in the islands of genomic divergence despite a gene flow in other regions rather than they retained the ancestral

divergence with a minimal gene flow (Weetman et al. 2012). These observations indicate that heterochromatic sequences diverge rapidly during speciation of malaria mosquitoes.

Figure 6. The pericentric and intercalary heterochromatin of polytene chromosomes shown on a standard cytogenetic map of *An. gambiae*. PH—pericentric heterochromatin, IHC—compact intercalary heterochromatin, IHD—diffuse intercalary heterochromatin (Sharakhova et al. 2010b).

Differences in the sequence and amount of heterochromatin, together with differences in the composition of heterochromatic proteins could contribute to chromosomal change leading to postzygotic isolation (Brown, O'Neill 2010). Fast changes in heterochromatic DNA can be accompanied by the rapid evolution of heterochromatic proteins. Although HP1 is an evolutionarily conserved protein, other heterochromatin- and centromere-associated proteins demonstrate rapid adaptive evolution (Talbert, Bryson, Henikoff 2004; Vermaak, Henikoff, Malik 2005). For example, an LHR protein encoded by *lhr* (*Lethal hybrid rescue*) colocalizes with HP1 in heterochromatic regions and has diverged extensively in sequence between *D. melanogaster* and *D. simulans* species in a manner consistent with positive selection. Interestingly, F1 hybrids between these species demonstrate altered chromatin structure, probably attributable to the effects of species-specific differences in TEs and other repetitive DNAs (Brideau et al. 2006), suggesting a role for heterochromatin in speciation. Because pericentric islands of genomic divergence between the M and S forms of *An. gambiae* are almost completely heterochromatic, it is possible that the mosquito heterochromatin has the elevated evolutionary plasticity and a role in speciation. One of the important tasks is to test if the X chromosome heterochromatin patterns are significantly differentiated among the *An. gambiae* complex species and the M and S forms.

Studies on *Drosophila* demonstrated the role of heterochromatin in controlling repeated sequences. For example, the COM locus, the centre organisateur de mobilisation, is a site in *Drosophila* that is responsible for the control of multiple retroTEs. It is located within the 20A region of the X heterochromatin, near the centromere (Desset et al. 2003). This locus is also known as the flamenco (flam) locus (Mevel-Ninio et al. 2007). The COM/flam locus has been found to control three retrotransposons in particular, ZAM, gypsy, and Idefix. In a normal strain of *D. melanogaster*, the COM locus is present and intact, thus leading to the silencing of these retrotransposons. In certain mutant strains – Rev and its derivatives, the COM locus is disrupted and leads to a high mobilization of these retrotransposons (Desset et al. 2008). The COM/flam

locus has been described as a master locus for the production of PIWI interacting small (24 to 30 nt long) RNAs (piRNAs) (Brennecke et al. 2007). piRNAs have been directly involved in the silencing of retrotransposons (Saito, Siomi 2010). Because inter-specific hybridization is often associated with transcriptional and epigenetics changes, and sometimes with mobilization of TEs (Michalak 2009), studying of piRNAs in hybrids may shed light on the mechanism of incompatibilities.

5. SIGNIFICANCE OF HIGH-QUALITY GENOME ASSEMBLIES FOR STUDYING MOSQUITO EVOLUTION

Draft genome assemblies of 16 *Anopheles* species (https://agcc.vectorbase.org/index.php/Main_Page) (Besansky 2008) require physical mapping to make them adequate for comprehensive genomic analyses related to studying various aspects of vectorial capacity. Assembling the genomes of other anophelines without a physical map, even with the help of the *An. gambiae* genome, will be extremely difficult given the extensive rearrangements of gene order among species (Cornel, Collins 2000; Sharakhov et al. 2002). Therefore, physical mapping of the polytene chromosomes will complement a sequencing project by facilitating the genome assembly. The quality of genome annotation of any organism depends highly on the completeness of the genome assembly. To perform full genome annotation for *An. gambiae*, one needs to identify all sequences that have a biological role in this malaria vector. Knowledge of the full complement of mosquito genes, regulatory elements, and repetitive elements is incomplete without information about what lies in those missing sequences. Creating physical genome maps is a crucial step in identifying the assembly gaps. The presence of haplotypes from cryptic species or isolated populations complicates genome assemblies. Although the *An. gambiae* PEST genome assembly has been improved by additional physical mapping of polytene chromosomes (Sharakhova et al. 2007), the abundance of misassembled M and S haplotype scaffolds still poses a serious problem for accurate annotation and functional characterization of the genome. The unmapped portion of the AgamP3 *An. gambiae* genome assembly comprises 42 Mb (Lawson et al. 2009; Megy et al. 2012) (15.6% of the genome) and includes both haplotype scaffolds and heterochromatin sequences (Sharakhova et al. 2010b). The importance of chromosome-based physical mapping for comparative genomics was emphasized in the article titled “Every genome sequence needs a good map.” The authors suggested looking “back in the future” for developing high-resolution physical maps as an important framework for the genome annotation and evolutionary analysis (Lewin et al. 2009). Physical maps and genome sequences allowed researchers to reconstruct ancestral genomes and determine the patterns and mechanisms of chromosomal evolution in mammalian and insect species (Murphy et al. 2005; Alekseyev, Pevzner 2007; Ranz et al. 2007; Bhutkar et al. 2008). Unmapped genome assemblies of anopheline mosquitoes will not be useful for reconstructing a gene order-based phylogeny and studying chromosome evolution in mosquitoes.

Anopheles gambiae belongs to a complex of seven sibling species, most of which are of less or no importance as malaria vectors. It is possible to determine an ancestral karyotype if outgroup arrangements are known (Green 1982; Lemeunier, Ashburner 1984). This argument is based on the idea that the chances of inversion re-use are very small. Moreover, phylogenies

based on inversion data are highly congruent with phylogenies based on nucleotide sequence data (O'Grady et al. 2001). A reconstruction of the *An. gambiae* complex phylogeny using fixed inversions and polytene chromosome maps of outgroup species has been attempted (Pape 1992). Although the sister group relationships of some species have been confirmed, the identification of the ancestral arrangements has failed because cytogenetic maps provide insufficient information on gene order and breakpoint locations. Therefore, higher resolution of gene order arrangements of an outgroup species and information on molecular position of inversion breakpoints are needed to reconstruct the inversion history in the *An. gambiae* complex. In a recent study, the breakpoint sequences of fixed overlapping inversions 2Ro and 2Rp in the *An. merus*—*An. gambiae* clade and homologous sequences in *An. stephensi*, *Aedes aegypti*, and *Culex quinquefasciatus* were obtained and analyzed (Kamali et al. 2012). The study demonstrated that all studied outgroup species had the gene arrangement identical to that in the 2Ro breakpoints of *An. merus* and in the 2R⁺ breakpoints of in *An. gambiae*. Because 2Ro and 2R⁺ uniquely characterize the *An. gambiae*—*An. merus* clade (Figure 1), these two species have the least chromosomal differences from the ancestral species of the complex as compared with other members. *Anopheles gambiae* and *An. merus* are vectors of human malaria and a more derived species, *An. quadriannulatus*, is not an effective vector. Thus, this study supports the repeated origin of vectorial capacity in the complex (Kamali et al. 2012).

The presence of readable polytene chromosomes in *Anopheles* species provides an uncommon opportunity for creating highly finished reference genome assemblies. The fruit fly research community made a special effort to create polytene chromosome maps for 12 species of genus *Drosophila* (Clark et al. 2007; Schaeffer, Group 2008). These maps allowed high-quality whole-genome assemblies with correct ordering of genic and nongenic DNA segments. A timely investment in producing reliable genome assemblies for major vectors will enable researchers to perform comprehensive comparative genomic analyses and will maximize investments in whole-genome resequencing of individual genomes from natural populations. The whole-genome resequencing approach has already been used to investigate patterns of the *An. gambiae* population divergence along a cline a latitudinal cline in aridity in Cameroon (Cheng et al. 2012).

CONCLUSION

Future mosquito genome sequencing projects, together with high-resolution physical mapping, will provide a better understanding of mechanisms of chromosomal rearrangements and roles of inversions and heterochromatin variations in creating biodiversity. The unequal chances of chromosome arms and lineages in generating and fixing inversions, as well as in heterochromatin modifications, may have serious consequences for differential adaptive and evolutionary plasticity of organisms. Therefore, it is important to understand the forces that govern the structural malleability of genomes. Although chromosomal inversions are abundant in malaria mosquitoes, their patterns and mechanisms remain a “black box” in vector biology. Research efforts to understand evolutionary mechanisms of chromosome evolution in vector species can be beneficial if conducted before new genomics strategies for vector control (e.g., using transgenic mosquitoes) are attempted. The following studies will significantly advance our understanding of chromosomal mechanisms of mosquito evolution.

A recent comparative study of the physical maps of *An. gambiae*, *An. funestus*, and *An. stephensi* demonstrated an excess of fixed inversions, as compared to a deficit of polymorphic inversions on the X chromosome (Xia et al. 2010). This phenomenon, if confirmed by whole-genome analyses of multiple species, could indicate that polymorphic inversions on the X chromosome are underdominant, as was theoretically predicted earlier (Charlesworth, Coyne, Barton 1987). Underdominant systems for gene drive could be used for replacement of defined target vector populations (Sinkins, Gould 2006). A rapid fixation of underdominant rearrangements could be an excellent tool for driving transgenes into natural populations of mosquitoes, if the heterozygotes are close to inviable or infertile. Molecular analysis of inversion breakpoints will inform about a mechanism for creating artificial rearrangements.

- [1] A comparative physical mapping has shown that natural selection favors adaptive gene combinations within polymorphic inversions on the 2R chromosome arm when three distantly related *Anopheles* species are exposed to similar environmental pressures (Sharakhova et al. 2011). This knowledge, obtained from multispecies genome sequence comparison, can be useful in the discovery of genes responsible for an association of inversion polymorphisms with phenotypic variations. If candidate genes are identified within a polymorphic inversion in one species, the orthologous genes in another species likely play a similar role in adaptation if they are captured by a polymorphic inversion involved in the parallel adaptation. Next generation sequencing analysis of transcriptome can be used to quantify expression differences between alternative inversion arrangements for different life stages and sexes of mosquitoes.
- [2] In malaria mosquitoes, the heterochromatin size and morphology vary significantly among species and within species (Gatti et al. 1977; Sharakhova, Stegnii, Braginets 1997; Sharakhova, Stegnii, Timofeeva 1997), possibly affecting mating behavior and fertility (Bonaccorsi et al. 1980). The mechanisms that constrain or promote evolutionary reorganizations of heterochromatin and nuclear architecture are largely unknown. What role do heterochromatin, noncoding RNAs, and nuclear architecture play in the speciation process? Can evolutionary changes in nuclear architecture explain the taxon and chromosome specificity in rates of rearrangements? Is organization and regulation of heterochromatic genes conserved in evolution? Instead of looking only at the DNA sequence (study in 1D), research efforts should take into account the chromatin structure (study in 2D) and the nuclear architecture (study in 3D).

The knowledge of the structure, function, and evolution of mosquito chromosomes will facilitate development of novel genome-based approaches for vector control. Full understanding of the mechanisms of genome rearrangement is crucial for developing novel approaches to manipulate chromosome structure and creating an artificial insect chromosome. The ecologically sound approaches to genetic modifications of insects using an artificial chromosome will significantly impact agriculture and public health.

Chapter 5

TRANSCRIPTIONAL DIFFERENTIATION ACROSS THE FOUR SUBSPECIES OF *DROSOPHILA MOJAVENSIS*

ABSTRACT

Local adaptation can play a fundamental role in the isolation of populations. While less well-studied than differentiation in sequence variation, changes in transcriptional variation during speciation also are fundamental to the evolutionary process. *Drosophila mojavensis* offers an unprecedented opportunity to examine the role of transcriptional differentiation in local adaptation. *Drosophila mojavensis* is a cactophilic fly composed of four ecologically distinct subspecies that inhabit the deserts of western North America. Each of the four subspecies utilizes necrotic tissue of different cactus host species characterized by distinct chemical profiles. The subspecies in Baja California, Mexico uses *Stenocereus gummosus* (Agria), in mainland Sonora it uses *S. thurberi* (Organ Pipe), in the Mojave Desert the host is *Ferocactus cylindraceus* (Red Barrel) and in Santa Catalina Island, USA, *Opuntia littoralis* (Prickly Pear) is the host. In this chapter we examine how the adaptation to the different environmental conditions across the four subspecies have shaped their transcriptional profiles. Using complete *D. mojavensis* genome microarrays we examined the transcriptome of third instar larvae from all four subspecies reared in standard laboratory media free of necrotic cactus-derived compounds. This experimental strategy focused on differences between constitutively expressed genes and not genes induced by necrotic cactus-derived compounds. The subspecies exhibited significant differential expression of genes that likely underlie the adaptation to different cactus hosts, such as detoxification genes (Glutathione S-transferases, Cytochrome P450s and UDP-Glycosyltransferases) and chemosensory genes (Odorant Receptors, Gustatory Receptors and Odorant Binding Proteins).

INTRODUCTION

Increasing levels of genetic isolation between populations can lead to the formation of new species. The mechanisms involved could be broadly characterized as pre-zygotic or post-zygotic (Coyne and Orr 2004). Although natural selection can play an active role in maintaining the isolation (e.g., hybrid inviability), natural selection does not necessarily have to be implicated in the genetic divergence of the populations (Dobzhansky-Muller incompatibility model) (Dobzhansky 1937; Muller 1942). In certain cases local adaptation can amplify the divergence across populations and hence accelerate the speciation process (Funk, Nosil, and Etges 2006; Nosil 2007; Schluter and Conte 2009; Nosil 2012). Among many other characters, the pattern of variation of the transcriptome can be shaped by the adaptation to local ecological conditions. Knowledge of the regulatory differentiation present in ecologically distinct populations therefore informs our understanding the role of transcriptional changes in speciation.

Cactophilic *Drosophila* offer a powerful system to assess how a combination of geographic isolation, local adaptation and in some cases sexual selection can play a critical role in speciation. One such example is that of the North American endemic cactophilic species, *D. mojavensis*. Similar to all cactophiles, *D. mojavensis* feeds, oviposits and develops in the necrotic tissues of certain cactus species (Fellows and Heed 1972; Heed 1978; Heed 1982; Ruiz, Heed, and Wasserman 1990). In general all *Drosophila* are saprophytic, and just like others, *D. mojavensis* feeds on the several yeast species that are known to inhabit the cactus necroses (Starmer 1982b; Starmer 1982a; Fogleman and Starmer 1985; Starmer et al. 1990). In the process of consuming yeasts the flies also ingest and are exposed to the tissues and chemical composition of the cactus host (Kircher 1982). *Drosophila mojavensis* has relatively recently (<0.5 million years ago) diverged from its cactophilic sister species, *D. arizonae* (Heed 1978; Machado et al. 2007; Matzkin 2008; Smith et al. 2012). Currently, *D. mojavensis* is composed of four geographically (Figure 1) and ecologically distinct subspecies (Pfeiler, Castrezana, and Reed 2009). Each subspecies utilizes a distinct cactus host, each characterized by distinct microflora and chemical profiles. Two of the subspecies, Baja California and mainland Sonora (hereafter Sonora), utilize columnar cacti belonging to the same genus, *Stenocereus* (*S. gummosus* and *S. thurberi*, respectively). The subspecies in the Mojave Desert utilizes Red Barrel (*Ferocactus cylindraceus*), while the subspecies in Santa Catalina Island utilized Prickly Pear (*Opuntia littoralis*).

Given the toxic nature of some of the compounds found in the cactus necroses that are inhabited by *D. mojavensis*, much of the earlier transcriptional work has focused on the dietary induction of cactus-related compounds (Matzkin et al. 2006; Matzkin 2012). This approach has helped identify genes whose expression and pattern of sequence variation appear to have been shaped by local adaptation (Matzkin 2008). In this chapter our goal was to remove the possible confounding effects of the induction of genes in response to cactus-derived compounds, and thus focus on transcriptionally fixed differences across the subspecies. Using *D. mojavensis* specific microarrays, we investigated the transcriptional profile of third instar larvae (reared in cactus-free media) from 22 isofemale lines representative of all four subspecies. We observed that genes associated with metabolism are a major component of the transcriptional differences across the host subspecies. Surprisingly, several chemosensory genes were among those who

exhibited significant within subspecies variation, although many of these also exhibited between subspecies differences.

Figure 1. Distribution of the four *D. mojavensis* subspecies.

ANALYSIS OF TRANSCRIPTIONAL DIVERGENCE

A total of 22 isofemale lines were used in this chapter, six each for the Catalina, Sonora and Mojave subspecies and four from Baja California (Table 1). Isofemale lines were reared in banana-molasses media in vials. A generation prior to the experiment five females and five males were placed in a banana-molasses 8-dram vial with granules of live yeast for 24 hours. After this period the ten adults were removed and placed in new vials for next 24 hours. A total of five of these replicate vials were established per each of the 22 isofemale lines. Approximately eight days after oviposition third instar wandering larvae were collected. RNA was extracted for a total of two replicates per each of the 22 isofemale lines. All samples were hybridized onto a custom *D. mojavensis* microarray based on the previously sequenced *D. mojavensis* genome (*Drosophila* 12 Genomes Consortium 2007). As originally described in Bono *et al.* (2011) the array consists of 71,998 60 oligonucleotide probes representing 14,519 annotated *D. mojavensis* genes. The large majority (96%) of the genes in the microarray were represented by 6 probes each. Expression intensities were first normalized using the Robust Multichip Average (RMA) method (Bolstad *et al.* 2003; Irizarry *et al.* 2003). Statistical analysis of the $\log_2$ transformed data was performed using a two-step mixed model ANOVA (Wolfinger *et al.* 2001). The first step of this method is a global (data set wide) analysis that removes probe-

and hybridization-specific effects, while the second step is a gene-specific analysis with subspecies and lines-within-subspecies as factors (also including microarray as a random factor). Given the 14,519 tests performed, significance was determined using the False Discovery Rate (FDR) method (Storey and Tibshirani 2003).

Two-way hierarchical clustering using the Ward method was performed for the differentially expressed genes. Clustering was first performed on mean expression intensity for each isofemale line and then by isofemale line. Analysis of the overrepresentation gene ontology (GO) terms was determined using the gene ontology enrichment analysis and visualization tool, GOrilla (Eden et al. 2007; Eden et al. 2009). Annotations of the *D. mojavensis* genome were based on the most current FlyBase annotation set (version FB2012-02) and those described in Matzkin (2012). Of the 14,519 *D. mojavensis* genes in the microarray we were able to obtain orthologous calls to *D. melanogaster* for just 10,685 genes. This smaller set of genes was used as the background gene set to test for overrepresentation of GO terms. For the purpose of examining overrepresented GO terms we set the *P*-value at less than 1×10^{-4} .

Figure 2. Two-level hierarchical clustering of expression intensities for the 14,519 genes examined. Expression intensities range from black (highest expression) to white (lowest expression). The tree indicates the transcriptional clustering across the 22 isofemale lines studied.

The entire transcriptional profile for each isofemale line can be observed in Figure 2. All expression data have been placed in the Gene Expression Omnibus under series entry #GSE41155. Although there are three exceptions (MJBC103, CI27 and ANZA10) all the isofemale lines tend to group together according to host subspecies (Figure 2). Genes with significant expression differences between and within subspecies are shown in Table 2. Regardless of the FDR cutoff used, the number of genes that exhibited a significant subspecies effect was roughly more than twice that showing significant within subspecies variation. We were interested in examining the most robust of differences between the subspecies and within subspecies and hence chose to use an FDR cutoff of 0.001 to assign significance. Even with this conservative FDR level, a total of 3,092 genes exhibited a significant subspecies effect, of which 655 also had a significant within subspecies effect (Figure 3). Among the genes with significant between subspecies differences include those involved in detoxification (Glutathione S-transferases, Cytochrome P450s, and UDP-Glycosyltransferases) and chemosensory (Odorant Receptors, Gustatory Receptors and Odorant Binding Proteins) (Table 3). For 660 genes we observed only a within subspecies effect (Figure 3). To examine subspecies pair differences, we performed a *post-hoc* test setting the FDR at 0.1% (Table 4). Comparisons using the mainland Sonora subspecies have the greatest number of observed transcriptional differences, while the comparison between Catalina Island and Baja California had the fewest (Table 4).

Table 2. Number of significant genes with significant subspecies and within subspecies variation [Line(Subspecies)] using different FDR cutoff values

	FDR		
	0.05	0.01	0.001
Subspecies	6343	4705	3092
Line(Subspecies)	2788	1971	1315

Figure 3. Proportion of genes with a significant within subspecies effect [Line(Subspecies)], subspecies effect, both within and between subspecies effects and not significant using and FDR cutoff value of 0.001.

Of the 3,092 genes with significant between subspecies differences, 2,033 had and orthologous calls to *D. melanogaster*. Results of the analysis of overrepresented Molecular Function and Biological Process GO terms are shown Figure 4. Most of the overrepresented GO terms appear to be associated with some aspect of metabolism. Also overrepresented were members of important detoxification gene families such as Glutathione S-transferases and Cytochrome P450s (within the heme-binding Biological Process GO terms). On the other hand, GO terms of genes that exhibited significant within subspecies variation (1,315 of which 744 had orthologous calls to *D. melanogaster*) were largely associated with chemosensory perception (Figure 5). The chromosomal location of the significant genes (Table 5) is significantly different ($\chi^2 = 14.2$, $df = 4$, $P = 0.0068$) from the expectation given the distribution of all genes in the *D. mojavensis* genome.

Table 3. Genes with significant between subspecies differences belonging to Gustatory Receptor (GR), Odorant Receptor (OR), Odorant Binding Protein (OBP), Glutathione S-Transferase (GST), Cytochrome P450 (P450) and UDP-Glycosyltransferase (UGT) gene families

ECOLOGICAL DIVERGENCE IN THE *D. MOJAVENSIS* TRANSCRIPTOME

The four host subspecies of *D. mojavensis* are presented by distinct ecological conditions, both biotic and abiotic in nature. These factors, among others (e.g., geographic isolation and sexual selection), have contributed to the morphological/structural (Etges et al. 2009; Pfeiler, Castrezana, and Reed 2009), life history (Etges and Heed 1987; Etges 1990), behavioral (Krebs

and Markow 1989; Markow 1991), molecular (Matzkin 2004; Machado et al. 2007; Matzkin 2008; Smith et al. 2012), biochemical (Matzkin 2005) and transcriptional (Matzkin et al. 2006; Matzkin 2012) variation in this species. Here we have identified the inherent modifications in the transcriptional profiles of the four *D. mojavensis* subspecies, independent of their diet.

Transcriptional regulatory differences accumulate as a function of isolation, having arisen by *cis* changes followed by *cis* and *trans* coevolution (Wittkopp, Haerum, and Clark 2004; Gordon and Ruvinsky 2012). As is clear from the clustering of the four subspecies by the entire transcriptome (Fig. 1), these subspecies have undergone a significant degree of transcriptional evolution. While we cannot specify the particular evolutionary force(s) that shaped the observed transcriptional divergence, the geographic isolation between the subspecies and historical bottlenecks (Smith et al. 2012) suggest that genetic drift could have influenced the transcriptional divergence (Stone and Wray 2001; Wray et al. 2003; Lynch, Scofield, and Hong 2005). At the same time, the known ecological differences between the subspecies ultimately can point to those genes whose expression difference may have been shaped by local adaptation. It is this adaptation to local conditions, partly via transcriptional changes, that contributes to the reduced success of migrant individuals, therefore aiding in the genetic isolation of the subspecies.

The necrotic cactus habitats utilized by each of the four host subspecies have marked chemical differences (Kircher 1982). In addition to the chemical composition of the different cactus species, the microfloral communities are critical in creating the chemical profile of what larvae and adult flies ingest (Starmer 1982b; Starmer 1982a; Fogleman and Starmer 1985; Starmer et al. 1990). Among these chemical differences are nutritional compounds, such as carbohydrates and lipids (Vacek 1979; Kircher 1982; Fogleman and Abril 1990). Of the 3,092 overall transcriptional differences across the subspecies, the significant majority had some role in metabolism (Fig. 3). Observed differences in metabolism-related genes observed thus may directly reflect adaptation to the different nutritional compositions of necrotic cactus hosts. As well as differences in nutritional compounds, several compounds present in cactus necroses can be toxic. Previous studies of transcriptional changes induced in response to necrotic cactus compounds revealed that many detoxification genes were affected (Matzkin et al. 2006; Matzkin 2012). In the present study we also observed expression differences in detoxification genes such as Glutathione S-transferases, Cytochrome P450 and UDP-Glycosyltransferases. Unlike in the prior studies, however, these differences are fixed and do not involve cactus compounds for their induction. Of course it is feasible that some of the significant gene expression differences across the subspecies could have been a result of a subspecies-specific response to the banana media. We reason that given the composition of the banana media (banana, yeast, molasses, corn syrup, antifungal and agar), many detoxification genes would not be influenced. Given that all the differences observed in the present study were seen in the absence of cactus compounds, many of the metabolism and detoxification genes underlying local adaptation appear to have been canalized with respect to their transcriptional profile.

TRANSCRIPTIONAL DIVERGENCE AND SPECIATION

The number of transcriptional differences differs drastically depending upon the particular subspecies analyzed (Table 4). Currently, several molecular studies (Machado et al. 2007;

Matzkin 2008; Smith et al. 2012) support the earlier idea by Ruiz *et al.* (1990) that the center of genetic diversity for *D. mojavensis* resides in Baja California. *Drosophila mojavensis* colonized mainland Sonora, Mojave and Catalina Island following its allopatric divergence from its sister species, *D. arizonae*, in Baja California. This historical model of the origin of the *D. mojavensis* subspecies predicts that, in the absence of selection, the fewest number of fixed transcriptional differences should involve comparisons involving Baja California and the other three subspecies, while the largest difference should occur between non-Baja California comparisons. Our observed pair-wise transcriptional differences (Table 4) support this prediction. Interestingly we observed that comparisons using the mainland Sonora subspecies exhibited the largest number of transcriptional differences. One major difference between the Sonora subspecies and the other three is the fact that it is the only one that is sympatric with its sister species *D. arizonae* (Fellows and Heed 1972; Ruiz, Heed, and Wasserman 1990). Reinforcement has markedly shaped the behavior of the sympatric Sonoran subspecies (Markow 1981) and this in turn could have potentially shaped its transcriptome. Given the expected multifaceted nature of reinforcement, it would be expected that several genomic regions would be affected, which would include transcriptional differences.

Chromosomal inversions have been proposed to play a role in speciation (Noor et al. 2001; Rieseberg 2001; Machado, Haselkorn, and Noor 2007). Inversions facilitate the persistence of linkage blocks that contain sterility factors and as a result higher levels of divergence should be expected around the inverted regions. We observed a greater number of expression differences in chromosomes 2 and 3 and lower number in chromosomes 1, 4 and 5 than expected by chance (Table 5). In *D. mojavensis* only chromosomes 2 and 3 are polymorphic and several of these inversions are fixed between the subspecies (Wasserman 1962; Mettler 1963; Johnson 1980; Ruiz, Heed, and Wasserman 1990). According to the model, elevated levels of fixed sequence differences should be observed around the inversion breakpoints, it is probable that these sequence differences could also affect transcriptional levels as it was observed here. Although we have not yet mapped the breakpoint sequences of the inversions in *D. mojavensis*, the increased level of transcriptional divergence in chromosomes 2 and 3 as a whole, provides us with some initial tantalizing evidence on the role of inversions in local adaptation and isolation in these subspecies. Current genome sequencing of the three remaining *D. mojavensis* subspecies by Matzkin will provide the information needed to begin to answer this question.

Although the largest number of transcriptional differences observed were between subspecies, approximately 9% the transcriptome exhibited significant within subspecies variation of which roughly half also differed between subspecies (Fig. 2). A disproportionate large number were involved with chemosensory pathways mostly dealing with odorant behavior (Fig. 4). Thirty Odorant Receptors had significant within subspecies variation, 11 of which also had significant between subspecies differences. Significant within subspecies variation could possibly be a result of relaxation of selection or balancing selection. This would suggest that at least directional selection has not played a role in shaping the pattern transcriptional variation in these chemosensory genes. Alternatively, the significant within subspecies variation could be result of the lack of stimuli (i.e., cactus derived compound) present in the rearing medium (banana-molasses food). Several chemosensory genes have been previously shown to respond to cactus rearing (Matzkin et al. 2006; Matzkin 2012). Given variation in host chemical composition, it is possible that for certain genes it would be advantageous to have a more plastic transcriptional profile. Additional studies comparing

cactus vs. non-cactus rearing are necessary to determine roles, if any, of chemosensory genes in the local adaptation of the different host subspecies.

CONCLUSION

Adaptation to local ecological conditions can be a potent driver of divergence between isolated populations (Funk, Nosil, and Etges 2006; Nosil 2007; Schluter and Conte 2009; Nosil 2012). *Drosophila mojavensis* offers a powerful system to investigate the role of local adaptation in the process of speciation. These subspecies already have accumulated a series of behavioral, morphological, life history and molecular differences (Etges and Heed 1987; Markow 1991; Matzkin 2005; Matzkin et al. 2006; Machado et al. 2007; Etges et al. 2009; Smith et al. 2012). Here we presented evidence that local adaptation might have been responsible in shaping the transcriptome of these ecologically different cactus host subspecies. Studies aiming to link genome level differences with the observed transcriptional differences as well as to functional, physiological and behavior differences are ongoing in our laboratories.

ABSTRACT

Acoustic signals produced to attract mates before, during, and after courtship are frequently involved with sexual selection, sexual isolation, and reproductive isolation in *Drosophila* spp. and other animals, yet few studies have revealed how courtship songs evolve in a larger phylogenetic context. Therefore, we mapped different acoustic components of courtship songs in the monophyletic *Drosophila buzzatii* species cluster onto an independently derived *period (per)* gene + chromosome inversion phylogeny to assess the concordance of courtship song evolution with species divergence. These cactophilic flies are distributed throughout several biomes in southern South America and include the sibling species *D. buzzatii*, *D. koepferae*, *D. serido*, *D. borborema*, *D. seriema*, *D. antonietae*, and *D. gouveai*. All seven species produced two song types; primary and secondary pulse songs, except for *D. borborema* and *D. gouveai* that produced no secondary songs. Courtship songs were characterized by analyzing six commonly studied acoustic components including burst duration (BD), carrier frequency (CF), pulse length (PL), pulse number (PN), inter-burst interval (IBI), and inter-pulse interval (IPI).

* Corresponding Author's Email: cassia.oliveira@lyon.edu.

Significant intra- and inter-specific song variation was observed for BD, PN, and IBI, while CF, PL, and IPI varied in a more species-specific manner, albeit with some overlap. Thus, some song components may be better species recognition signals than others. Multivariate clustering analyses resolved all species into distinct, non-overlapping groups. Mapping individual song traits (BD, IBI, and IPI) as well composites of these song variables onto our (*per*) gene + chromosome inversion phylogeny revealed no phylogenetic signal when different comparative mapping methods were used. Hence, the evolution of courtship songs in *D. buzzatii* cluster species was uncorrelated with the degree of species divergence. These findings reinforce previous observations that courtship songs evolve rapidly enough to erase any signature of evolutionary affinity between closely related animal species.

INTRODUCTION

In a number of *Drosophila* species, courtship “love” songs have been implicated in promoting sexual isolation between species (Ewing 1989; Ritchie et al. 1999). Despite the potential importance of courtship songs in the speciation process and that songs have been characterized in over 100 *Drosophila* species (Hoikkala 2005), only a few studies have investigated the correlation between song traits and species phylogenetic history (Ewing and Miyan 1986; Gleason and Ritchie 1998; Etges 2002). Comparative studies involving mate signaling cues in closely related species are crucial to unraveling not only which traits are repeatedly involved in the early stages of species formation, but also determining their divergence rates across taxa (Etges 2002; Coyne and Orr 2004). In short, we are interested in identifying key behavioral traits that are responsible for large-scale diversification of species. Thus, we analyzed the evolution of quantitative differences in courtship song traits in the *D. buzzatii* cluster, a group of recently diverged species, in order to assess the concordance of love song evolution in relation to patterns of species divergence in a phylogenetic context.

During courtship, males of most *Drosophila* species produce acoustic signals, courtship love songs, by vibrating their wings in attempts to gain female acceptance and successful copulation (Ewing 1983). Courtship songs are typically species-specific in the majority of *Drosophila* species (Cowling and Burnet 1981; Cobb et al. 1988; Ritchie and Gleason 1995), and so acoustic signaling is thought to allow courting adults to ascertain the appropriateness of attempting to mate with a member of the opposite sex (Ewing 1989; Saarikettu et al. 2005; Mendelson and Shaw 2012), even though these species differences may evolve by sexual selection (Ritchie and Gleason 1995; Ritchie et al. 1998).

Drosophila love songs are typically characterized by low frequency pulses that can be produced individually or in structured bursts. Some species, such as those in the *D. melanogaster* group, have two types of song, pulse song and sine song (Cowling and Burnet 1981). In the *D. repleta* group, two kinds (A and B) of pulse songs have been described where A songs have short inter-pulse intervals (S-IPs), and B songs have longer inter-pulse intervals (L-IPs) (Figure 1). However, not all species within the group exhibit both song types, and variation between species is considerable (Ewing and Miyan 1986).

The rate of pulse production measured by the inter-pulse interval or IPI has been shown to be a common mate recognition signal recognized by female *Drosophila*. However, other courtship song traits have been found to be species-specific in *Drosophila*, including burst duration, inter-burst interval, pulse number per burst, sine song, cycle number per pulse, and intra-pulse frequency (Bennet-Clark and Ewing 1969; Kyriacou and Hall 1980; Ritchie and Gleason 1995; Byrne 1999; Yamada et al. 2002; Etges et al. 2006). Females can use one or more love song components when selecting among potential mates (Kyriacou and Hall 1982; Tomaru et al. 1995; Ritchie, et al. 1998). For example, *Drosophila montana* females will not mate with wingless males, implying that courtship song is an obligatory component of courtship in this species (Liimatainen et al. 1992). In *D. melanogaster*, male courtship song is not necessary for mate recognition, since wingless males can copulate, even though the time it takes to achieve copulation is longer than for control males (von Schilcher 1976). Using recorded love songs in playback experiments has shown a role for courtship song in sexual isolation between different populations or species by exposing females to wingless males and then playing different types of songs. The large role of love songs has been confirmed in these studies where male mating success was restored or increased by play-back of songs of the same population or species. For example, this is the case for two other members of the *D. repleta* group, *D. mojavensis* and *D. arizonae* (Byrne 1999).

PHYLOGENY OF *D. BUZZATII* CLUSTER SPECIES

The species of the *D. buzzatii* cluster belong to the large *D. repleta* group (Ruiz and Wasserman 1993; Durando et al. 2000; Oliveira et al. 2012) including *D. buzzatii*, *D. koepferae*, *D. serido*, *D. borborema*, *D. seriema*, *D. antonietae*, and *D. gouveai*. All are closely related “sibling” species that form a monophyletic group (Manfrin and Sene 2006). These species are endemic to South America, except for *D. buzzatii* that has a cosmopolitan distribution due to its association with species of *Opuntia* cactus that have been propagated around the world for fruit production (Wasserman 1992).

The monophyly of the *D. buzzatii* cluster was first defined on the basis of a complex arrangement of chromosomal inversions (Ruiz and Wasserman 1993), yet only four fixed inversions can be used for species identification (Ruiz et al. 2000; Manfrin et al. 2001) (Figure 2). Other traits including mtDNA COI gene sequences (Manfrin, et al. 2001) and Xanthine dehydrogenase (*Xdh*) nucleotide sequences (Rodriguez-Trelles et al. 2000), as well as wing morphology (Moraes et al. 2004) have also been used to infer phylogenetic relationships among these species. Phylogenetic analysis using mtDNA COI indicated that the *D. buzzatii* cluster was a well-supported monophyletic group (Manfrin, et al. 2001; de Brito et al. 2002), but these mtDNA sequences did not help to resolve the pattern of species relationships within this group. At present, sequence variation in the *period* (*per*) gene (Franco et al. 2010) has produced a phylogeny that best resolves these branching patterns. The *per* phylogeny also reinforced the monophyletic nature of this cluster, but more importantly it resolved the relationships of *D. gouveai*, *D. borborema* and *D. seriema*, which had been difficult to understand when chromosomal inversions and mtDNA sequences were used.

Figure 1. A-G. Typical courtship song of *D. buzzatii* species composed of pulses arranged into bursts. Oscillograms are used to illustrate the *Drosophila* courtship song terminology. (A) Fifty seconds of pulse song showing both primary and secondary song. IBI = inter-burst interval. (B) Single burst of primary song showing composed of 52 pulses. (C) Expanded view of B showing the first 12 polycyclic pulses. IPI = inter-pulse interval. (D) Two bursts showing primary and secondary song, respectively. (E) Enlarged view of D. (F) Oscillogram of six bursts: three bursts of primary song intercalated by three bursts of secondary song. (G) Spectrogram of the oscillogram showed in F. Bursts of primary song present higher frequency than the bursts of secondary song.

HOST CACTUS, BIOGEOGRAPHY AND ECOLOGY OF *D. BUZZATII* CLUSTER SPECIES

The *D. buzzatii* cluster species are distributed over a vast geographical area in South America, ranging from northeastern Brazil to Paraguay, Bolivia and Argentina (Figure 3). The vegetation in these areas includes the morpho- climatic biomes of caatinga (thorny scrub), cerrado (savannah), Atlantic forest, and Chaco. Like other cactophilic species belonging to the *mulleri* subgroup of the *D. repleta* group, *D. buzzatii* cluster species use fermenting cactus tissues as feeding and breeding substrates, and the level of host specificity varies among the different species (Sene et al. 1982; Ruiz, et al. 2000; Kokudai et al. 2011).

The ecology and biogeography of the *D. buzzatii* cluster species, as well as varying levels of genetic divergence within this clade make the *D. buzzatii* cluster an ideal system to address questions regarding how mate recognition systems evolve in the early stages of species divergence. First, we recorded and described the courtship songs of these species and used a comparative approach to assess whether courtship song evolution was correlated with species divergence. Our results revealed strong species-specific differentiation in multiple acoustic characteristics of male courtship songs signifying rapid evolution in this central component of acoustic courtship signaling.

DESCRIPTION OF COURTSHIP SONGS AND COMPARATIVE METHODS

We recorded the courtship songs of all seven species of the *D. buzzatii* cluster and quantified variation in courtship song components (Figure 3). Fly stocks and handling procedures are described in Oliveira et al. (2011). All flies were aged at least 8 days before use to ensure sexual maturity (Bizzo 1983; Moraes 1992). Courtship songs of ten males of each species were recorded with an ultra-sensitive microphone (Bennet-Clark 1984) in an acrylic chamber (3 x 3 x 1 cm³) as described by Sene and Manfrin (1998). Each male was housed with two virgin females of the same species and the wings were removed from the females prior to recording. Temperature inside the recording chamber was monitored continuously with a digital thermometer because courtship songs can be temperature dependent (Byrne 1999; Ritchie et al. 2001). The time of day of recording was not controlled for. Approximately three minutes of song were recorded for each male. We digitized the song recordings at 8 KHz using Sonic Sound Forge software (2006, Creative Software Inc., Madison, Wisconsin, USA).

We analyzed courtship song components with Raven Pro 1.3 software (2003, Cornell Laboratory of Ornithology, Ithaca, New York, USA). All song measurements were made directly from the waveform tracings from Raven. For each male, five bursts of each type of song (i.e., primary and secondary) were analyzed but not all males produced a secondary song. A total of six song components was analyzed for each type of song including burst duration (BD), carrier frequency (CF), pulse number (PN), and inter-burst interval (IBI) that were measured from five randomly selected bursts. For pulse length (PL) and inter-pulse interval (IPI) five randomly selected pulses or inter-pulses, respectively, were measured per burst (Table 1, Figure 1).

Figure 2. Left side: Consensus phylogeny based on chromosomal inversions for *D. buzzatii* species cluster. Male genitalia (type A – E) are according to Silva and Sene (1991). Chromosomal inversions, shown above the tree branches, were based on the work of Ruiz et al. (1997; 2000). Black branches characterize species that have both primary and secondary song, while white branches represent species that possess only primary song, i.e., have lost secondary song. Right side: Typical wave pattern of the male courtship songs of the species of the *D. buzzatii* cluster.

Song differences among species were assessed for all song variables using PROC GLM (SAS Institute Inc. 2004) and temperature effects during recording were evaluated with analysis of covariance (ANCOVA). Species were considered a fixed effect and temperature was log transformed to improve normality. Principal components analysis (PCA) was used to reduce the dimensionality of the data in PROC PRINCOMP, and canonical discriminant function analysis (CDF) was used to help visualize species differences with PROC CANDISC. We used both data corrected for temperature variation and the residuals in PCA and CDF analysis. Principal Components (PCs) and canonical variates (CVs) were later used for character mapping analysis (see below).

Table 1. Definition of song parameters analyzed in the species of the *D. buzzatii* cluster

Song Parameter	Abbreviation	Unit	Definition
Burst Duration	BD	Milliseconds (ms)	The time between the first and last pulse in a burst.
Carrier frequency	CF	Hertz (Hz)	Highest peak frequency from a fast Fourier transformation.
Pulse Length	PL	Milliseconds (ms)	The length of a pulse.
Pulse Number	PN	----	Number of pulses per burst.
Inter-Burst Interval	IBI	Milliseconds (ms)	The time between the end of a burst and the beginning to the next one.
Inter-Pulse Interval	IPI	Milliseconds (ms)	The time between pulses, measured from peak-to-peak.

For each male five bursts were analyzed for each type of song (primary and secondary song).

Phylogenetic Reconstruction

Phylogenetic relationships for the seven *D. buzzatii* cluster species were reconstructed using chromosomal inversion differences (Ruiz et al. 1997; Ruiz, et al. 2000) and nucleotide variation in a 443 bp fragment of the X linked *period* (*per*) gene (Franco, et al. 2010). Two outgroup species, *D. mojavensis* and *D. hydei* were also included. Because no song data were available for *D. hydei* this species was removed before the tree was used for phylogenetic analysis of song evolution. Three song components were available for *D. mojavensis*, i.e., BD, IBI, and IPI, from Etges et al. (2007). Because we were also interested in the song evolution for *D. mojavensis* as well as its effects as an outgroup, we kept this species in the character reconstruction analysis when individual song components were mapped onto the phylogeny, but removed it when PCs or CVs were used (see below).

Figure 3. Partial view of South American map showing the geographic distribution of the species of the *D. buzzatii* cluster and the four major vegetation types with which these species are associated. The distribution of *D. buzzatii* is not marked because this species is found in all areas where the other species occur. Numbers represent the description for each of the species used in the courtship song analysis, i.e., species name, stock number, locality and year of collection. (1) *D. antonietae* (J41P1M), Serrana, São Paulo, 1999; (2) *D. borborema* (N70), Junco do Seridó, Paraíba, 2008; (3) *D. buzzatii* (J26A45), Osório, Rio Grande do Sul, 1998; (4) *D. gouveai* (J78M1), Ibotirama, Bahia, 2001; (5) *D. koepferae* (B20D2), Tapia, Tucumán; (6) *D. serido* (J92A91M), Milagres, Bahia, 2002; (7) *D. seriema* (D73C5BM), Morro do Chapéu, Bahia, 1990. Except for *D. koepferae*, from Argentina, all other species were collected in Brazil.

Phylogenetic analysis using the combined data was performed using PAUP* 4.0 (Swofford 2000) as in Oliveira et al. (2011). Maximum parsimony was used to search for optimal tree(s) and heuristic searches were carried out with 100 random addition analyses and tree bisection reconnection (TBR) branch swapping. Nodal support was obtained using bootstrap analysis (1,000 replicates).

Mapping Song Traits onto the Phylogeny

Patterns of courtship song evolution were inferred by mapping individual song traits, i.e., BD, IBI, and IPI, Principal Components (PCs), and canonical variates (CVs) onto the reconstructed phylogeny using Mesquite 2.74 (Maddison and Maddison 2010). Because some song components were temperature dependent (e.g., Ritchie, et al. 2001; Etges, et al. 2007), all six song components were regressed against temperature using PROC REG to generate predicted (PRD) and residual (RES) values used in character mapping. These values were mapped onto the first of two most parsimonious trees instead of the strict consensus tree because one of the models used, Squared Change Parsimony Gradual (see below), requires branch length information. Character reconstruction analysis was used to infer phylogenetic signal and was performed using three parsimony methods, Linear Parsimony (LP), Squared Change Parsimony Gradual (SCPG), and Squared Change Parsimony Punctuated (SCPP). In addition to these three parsimony methods, we also used the test for serial independence (TFSI) to detect phylogenetic signal as described in Abouheif (1999) using Phylogenetic Independence 2.0 (Reeve and Abouheif 2003). Phylogenetic signal was used as a measure of congruence between the phylogeny and variation in the song variables.

We tested the null hypothesis that courtship songs have evolved independently of species evolution due to non-phylogenetic influences such as developmental noise, ecological effects (e.g., rearing conditions), or species-specific sexual selection. Our alternative hypothesis was that positive phylogenetic signal should be observed due to the phylogenetic affinities of these species and song traits. The presence of phylogenetic signal was tested with all three parsimony methods by randomly modifying the most parsimonious tree, named here as a reference tree (Oliveira, et al. 2011). The terminal taxa on the reference tree were reshuffled 10,000 times to generate a population of random trees for each of the variables tested, i.e., PCs, CVs, and individual variables (BD, IBI, and IPI). These random trees with reshuffled taxa were then compared with the reference tree to test whether the mapped variables were more conserved than expected by chance alone. Presence of phylogenetic signal was inferred if the number of parsimony character steps in the reference tree was less than in 95% of the trees with reshuffled taxa and fell on the extreme left of the distribution. For all three parsimony methods and TFSI, *P* values were corrected for multiple comparisons via false discovery rate (FDR) analysis (Benjamini and Hochberg 1995; Laurin et al. 2009).

Differences in Courtship Song Components

Male courtship songs consisted of low-frequency, polycyclic pulses arranged into pulse trains or bursts (Figures 1 and 2). Courtship songs were produced by vibration of both wings during courtship and until copulation, but no song was produced during or after copulation. Primary song was produced during most of the courtship sequence and secondary songs were usually produced later in courtship, immediately before copulation. Secondary song was absent in males of *D. borborema* and *D. gouveai*. Ambient recording temperature ($\bar{X} \pm \text{SD} = 25.33 \pm 1.01^\circ\text{C}$, $N = 70$, range $23 - 27^\circ\text{C}$) had little significant effect on variation in any of the song components except for primary song IPI (Table 2). ANCOVA revealed heterogeneity of slopes for a few song components caused by different species. Along with some missing data and only

10 males per species recorded, we observed differences in significance between Type I and Type III sums of squares for species differences (results not shown) and statistical significance for the overall model sums of squares. We report Type III sums of squares and their significance in Table 2 to be conservative, but Type I sums of squares for BD, CF, PN, IBI, and IPI were all statistically significant. Further, significant pair-wise species differences were observed when least square means were analyzed (See Figure 4). As the ANCOVAs used contained one fixed effect (species), temperature as a covariate, and a species X temperature interaction term, we concluded that Type I sums of squares were appropriate for revealing species differences in these song components. Differences among species as well as differences in type of song for each song component are described below. Since *D. borborema* and *D. gouveai* lacked secondary songs, no comparison for type of song was available for these species.

Pair-wise comparisons using least square means revealed that burst duration was variable for several of the species pairs (Figure 4A). Further- more, BD did not vary consistently for individuals of the same species or even in the same individual. In fact, song bursts in the same individual had different shapes, amplitudes and durations (Figure 2). Mean BD for primary song ranged from 129.34 ms to 660.44 ms, and for secondary song, ranged from 78.67 ms to 440.17 ms (Table 3). Except for *D. borborema*, CF was relatively similar among the other species (Figure 4B). For all species, CF was characterized by low frequency peaks with mean CF for primary song ranging from 213.13 Hz to 467.51 Hz, and for secondary song ranging from 274.67 Hz to 379.69 Hz (Table 3). Pulse length or pulse duration was more conserved for primary song than for secondary song (Figure 4C). All seven species produced songs with polycyclic pulses consisting of two to four cycles per pulse. Mean PL for primary song ranged from 5.25 ms to 6.14 ms, and for secondary song, from 6.22 ms to 7.75 ms (Table 3).

Pulse number influenced burst duration. For instance, *D. borborema* produced long bursts (Figure 4A), which had more pulses (Figure 4D). Mean PN for primary song ranged from 9.6 pulses to 42.3 pulses (Table 3). For secondary song, mean PN ranged from 5.8 pulses to 24.3 pulses (Table 4). Because of its correlation with burst duration, pulse number was also highly variable. Inter-burst interval, measured as the distance between bursts, was difficult to calculate because some males stopped and started singing multiple times. Least square mean comparisons revealed that *D. borborema* had the highest IBI values. Even though IBI for secondary song was not statistically different among species ($P = 0.2482$), there was variation among individuals of the same species, especially for *D. antonietae*, as indicated by a large standard error (Figure 4E). Mean IBI for primary song ranged from 347.56 ms to 1348.22 ms, and for secondary song, from 480.73 ms to 1536.84 ms (Table 3).

Based on least square mean comparisons for primary song, *D. borborema* had the highest mean IPI, which was significantly different from all other species (Figure 4F). For secondary song, *D. buzzatii*, *D. koepferae*, and, *D. seriema* had the highest mean IPI followed by *D. serido* and lastly by *D. antonietae*. Mean IPI for primary song ranged from 7.92 ms to 14.20 ms, and for secondary song, from 8.85 ms to 12.30 ms (Table 3). Differences in IPI between primary and secondary songs were significant among the five species that possessed both types of songs ($P = 0.0113$). Significant pair-wise species differences were observed when least square means were analyzed, but only *D. buzzatii* showed significant differences for both song types where IPIs were shorter for primary song and longer for secondary song (Figure 5). Therefore, except for *D. buzzatii*, the other four species had unimodal IPIs, i.e., just one type of IPI. Bimodal IPIs, i.e., short and long IPIs, are considered a characteristic of the *D. repleta* group (Ewing and Miyan 1986).

See Figure 4 for least square mean differences between species. Lgtemp = $\log_{10}$ temperature.

Principal components analysis (PCA) revealed that the five principal components (PCs) accounted for 96% of the variation in the data for the seven species. The first principal component (PC1) accounted for 51% of the variance and was mainly driven by the differences between primary and secondary songs. PC1 scores were all negative for primary song traits (except for carrier frequency), and positive for secondary song traits (Table 4). Such differences were accentuated because secondary song was absent in some males and completely absent in *D. borborema* and *D. gouveai*. Accordingly, PC1 separated these two species from the others (Figure 6). The second principal component (PC2) accounted for 20% of the variation and separated species largely based on differences in primary songs traits, i.e., BD, CF, PN, and IBI. The third and fourth PCs, which represented 16% and 6% of the variation, respectively, were also mostly influenced by differences in primary songs (Table 4).

Canonical discriminant function (CDF) analysis using the residuals of the song characters yielded significant multivariate differences among species (Wilks $\lambda = 0.0000$, $F = 6.13 \times 10^{11}$, $P < 0.0001$). The first three canonical variables accounted for 98% of the total variation in courtship songs. As observed with PC analysis, the first canonical variate (CV1) was largely influenced by differences in type of song, primary and secondary, and the second and third canonical variates (CV2 and CV3) expressed differences among species as a result of variation in primary song (results not shown). Altogether, the results from PCA and CDF analysis confirmed that courtship songs were species-specific in the *D. buzzatii* cluster and primary song was mainly responsible for species differences.

CHARACTER MAPPING ANALYSIS OF COURTSHIP SONG

We used the first of two most parsimonious trees to perform the character reconstruction analysis (Figure 7). No phylogenetic signal was observed for any of the song traits mapped onto the phylogeny using either temperature corrected data or the residuals, i.e., individual song traits (BD, IBI, and IPI), CVs or PCs, using four different reconstruction methods (Table 5). Even though *D. mojavensis* is not closely related to the *D. buzzatii* cluster, this species had long bursts similar to *D. buzzatii*, *D. serido*, and *D. seriema*. However, *D. koepferae*, closely related to *D. buzzatii*, had short bursts (Figure 7A). Furthermore, *D. borborema* and *D. seriema* are closely related, but the former had the longest bursts of all species (Table 3, Figure 7). Similar differences were observed for IBI and IPI (Figure 7B, C) and the other variables (PCs and CVs). When PCs and CVs were mapped onto a phylogeny with or without *D. mojavensis* as an outgroup, phylogenetic signal was not detected (Table 5) indicating that this species did not influence the results. Overall, our results demonstrated no congruence between species differences in these song traits and phylogenetic structure in this clade of *Drosophila* species.

Figure 4. A-F. (Continued).

Figure 4. A-F. Least square means $\pm$ SE of six song components. A) Burst duration, B) Carrier frequency, C) Pulse number, D) Pulse length, E) Inter-burst-interval, and F) Inter-pulse-interval. Nonsignificant means share the same letter. Interspecific comparisons were performed for primary and secondary song separately.

Figure 5. Differences in IPI, inter-pulse interval, between primary and secondary songs among five species using least square means $\pm$ SE. No comparison was performed for *D. borborema* and *D. gouveai* because these species lacked secondary song. Nonsignificant means share the same letter.

Figure 6. Three dimensional plot of the *D. buzzatii* species cluster based on the first three principal components (PCs) obtained from six song components (see Table 1). Altogether, the first three PCs explained 87% of the variance in the data (PC1 = 51%, PC2 = 20%, and PC3 = 16%).

Variables were generated using values corrected for temperature variation. Only the first five principal components (PC1 – PC5) are shown that accounted for 96% of the variation in the data. Values in parentheses are the percentages of the variance explained by each PC. Numbers in bold represent the song traits that most contributed to the PC scores. See Table 1 for description of song traits. BD = burst duration; CF = carrier frequency; PN = pulse number; PL = pulse length; IBI = inter-burst interval; IPI = inter-pulse interval; PS = primary song; SS = secondary song.

Individual song components, i.e., burst duration (BD), inter-burst interval (IBI), and inter-pulse interval (IPI), were mapped onto a phylogeny that included the seven species of the *D. buzzatii* cluster plus *D. movajensis* as an outgroup. Furthermore, CDF analysis and PC analysis were used to obtain canonical variates (CVs) and principal components (PCs). These variables were also mapped onto a phylogeny, but this time it did not include an outgroup. All variables mapped onto the phylogeny were based on predicted (PRD) and residual (RES) values. Three different parsimony methods were used in Mesquite: linear parsimony (LP), squared-change parsimony assuming a gradual model of evolution (SCPG), and squared-change parsimony with a punctuated model of evolution (SCPP). In all three models, presence of phylogenetic signal for each character was assessed by comparing the mean parsimony character steps from the reference tree (as shown on Figure 7) with those of a population of random trees. Terminal taxa were reshuffled 10,000 times to generate the random trees. Phylogenetic signal was positive when the mean parsimony character steps for the reference tree were significantly smaller than the mean parsimony character steps for the random trees. The detection of phylogenetic signal was also examined with the test for serial independence (TFSI) run with 1,000 replicates using the program Phylogenetic Independence 2.0. P-values were adjusted using false discovery rate (FDR) analysis. No p values were significant after the adjustment.

Figure 7. A-C. Phylogenetic character mapping using the linear parsimony model. This phylogeny represents a most parsimonious tree (one of two trees) of species of the *D. buzzatii* cluster inferred from chromosomal inversions (Ruiz et al. 1997; 2000) and *period* gene (Franco et al. 2011). *D. mojavensis* was used as an outgroup species. A) Burst Duration; B) Inter-Burst-Interval; and C) Inter-Pulse-Interval. Bootstrap values (shown above the nodes) were based on 1,000 replicates and 100 random additions. Only bootstrap values above 50% are shown.

CONCLUSION

Our comparative analysis of quantitative variation in male courtship songs revealed that song evolution was uncorrelated with the phylogenetic relationships among species. Mapping primary and secondary pulse songs types onto the phylogeny revealed that the presence of two songs is ancestral in the *D. buzzatii* cluster (Figure 2). These findings are in agreement with Ewing and Miyan (1986), who suggested that two song types is a primitive character state in the *D. repleta* group. They also proposed that differences in IPI (short and long IPIs) were responsible for the differences between A and B songs in species of the *D. repleta* group. We did not find clear correspondence between A and B songs and our designations of primary and secondary songs. Only *D. buzzatii* males produced significantly different primary and secondary songs, i.e., short IPI for primary song and long IPI for secondary song (Figure 5). In the other four species that possessed both types of songs, IPIs were unimodal. Ewing and Miyan (1986) also reported that *D. buzzatii* produced A song, but lacked B song. Males of the strain of *D. buzzatii* that we analyzed clearly presented two types of songs, so it is likely that there is intraspecific variation in song types for *D. buzzatii*. Intriguingly, they also described *D. mojavensis* as having only A song, but other studies have found both types of songs (Byrne 1999; Etges, et al. 2006).

The high levels of variation in courtship song among the different species of the *D. buzzatii* cluster are in agreement with other studies involving closely related *Drosophila* species (Cowling and Burnet 1981; Ewing and Miyan 1986; Hoy et al. 1988; Hoikkala et al. 1994; Tomaru and Oguma 1994; Ritchie and Gleason 1995; but see Noor et al. 2000). These findings have suggested that aspects of courtship behavior and mate recognition can be more distinct than morphology or other traits in closely related species (Butlin and Ritchie 1994; Mendelson and Shaw 2005). In fact, it is common for cryptic species to show low levels of genetic divergence in contrast to major differences in courtship behavior phenotypes (Henry et al. 2002). These patterns of differentiation are consistent with a significant role of sexual selection promoting sexual isolation and speciation (Panhuis et al. 2001). However, Noor et al. (2000) observed a lack of divergence in courtship songs between recently diverged subspecies *Drosophila pseudoobscura pseudoobscura* and *D. p. bogotana*, implying that rates of evolution in courtship songs may vary among different species groups. Also, Costa et al. (2000) observed low levels of intraspecific courtship song variation in *D. meridionalis*, also a member of the *D. repleta* group, despite the fact that karyotypic differentiation has been reported in different populations. Future studies will have to include fine-scale intraspecific, population level studies to gauge accurate rates of courtship signal and male-female signaling system evolution.

Similar to many other *Drosophila* species, courtship songs in the *D. buzzatii* cluster were characterized by low-frequency songs (Figure 1) limiting the use of male song to close-range courtship (Ewing 1983). Hawaiian *Drosophila* species are a remarkable exception, since these species produce high-frequency songs (Hoy, et al. 1988). High levels of quantitative variation were observed within *D. buzzatii* cluster species for some of the song components, e.g., burst duration and pulse number (Figure 4A, D), implying that these two traits may not be reliable species-specific signals as they would not serve as consistent species recognition signals. Furthermore, for song traits that were more species specific, e.g., pulse length and IPI (Figure 4C, F), there was significant overlap among species suggesting that females may use more than one song component during mate and/or species recognition. Despite large variation at the

individual level, courtship songs, particularly primary songs, were species-specific in the *D. buzzatii* cluster (Table 2, Figure 6). Certainly, the large differences in male courtship songs are likely to play a role in interspecific sexual isolation in the *D. buzzatii* cluster (Oliveira et al., unpubl. data), but song playback experiments with wingless males (Byrne 1999) have yet to be performed.

In the *fasciola* subgroup, a basal clade of species in the *D. repleta* group, Costa and Sene (2002) reported that IPI was species-specific with little intraspecific variation, suggesting a potential role in species recognition. In *D. montana*, females prefer songs with short pulses and high carrier frequency (Ritchie et al. 2005). In *D. ananassae* and *D. pallidosa* females recognize the frequency spectra of bursts (determined by inter-pulse-interval, intra-pulse-frequency and cycles per pulse) as a species-specific signal rather than individual song components (Yamada, et al. 2002).

EVOLUTION OF COURTSHIP SONGS

No phylogenetic signal was observed when we mapped quantitative song traits onto an independently derived phylogeny of the *D. buzzatii* cluster (Table 5, Figure 7) consistent with rapid evolution of male courtship songs. Although rates of species divergence in this group given their genetic affinities have been well described (e.g., Manfrin and Sene 2006), our analyses need to be broadened to a larger sampling of *D. repleta* group species in order to assess the validity and generality of our conclusions. Few comparative studies have investigated the evolution of behavioral traits involved in mate recognition and reproductive isolation (e.g., Ewing and Miyan 1986; Kusmierski et al. 1997; Gleason and Ritchie 1998; Henry et al. 1999; Etges and Noor 2002; Symonds and Elgar 2004; Grace and Shaw 2012). Even scarcer are studies that have mapped quantitative variation, rather than categorical differences, in behavioral traits onto a phylogeny. This is in part because it has been difficult to identify sufficient numbers of species clusters whose members are in different stages of reproductive isolation and for which there is comparative data for phenotypes involved with pre- and/or postmating isolation. Furthermore, the long-standing view that the evolution of behavioral traits is weakly or uncorrelated with phylogeny (e.g., Atz 1970; Baroni Urbani 1989; Blomberg et al. 2003) has certainly contributed to a *a priori* view that all behavioral traits are labile.

In their comparative study of the courtship songs in 22 species of the *D. repleta* group, Ewing and Miyan (1986) mapped the evolution of song types, A and B songs, onto a phylogeny based on chromosomal inversions. They observed that presence of two song types was ancestral in the group, but over evolutionary time some species have lost one of the song types while in others B song has become more complex. Etges (2002) mapped song types onto the phylogeny of the group using an available species phylogeny (Durando, et al. 2000), and showed that song type evolution was not concordant with the observed phylogenetic relationships among species and has been characterized by diversification, character loss, and reversal. Contrasting results have been found in other animal species regarding the evolution of courtship songs. In the *Drosophila willistoni* group, Gleason and Ritchie (1998) observed that song divergence was variable and not correlated with genetic divergence. In green lacewings songs were homoplastic (Henry, et al. 1999; 2012), while in oropendola birds songs were more conserved (Price and Lanyon 2002).

The inclusion of more comparative data is needed to calibrate rates of song evolution. Clearly courtship songs have evolved more rapidly than species diversification in several *Drosophila* species groups, but other factors must be involved in shaping larger phylogenetic trends in song evolution. The *D. repleta* group is a potentially useful group for this analysis since it is one of the largest monophyletic groups of *Drosophila*, with over 100 species (Throckmorton 1982; Vilela 1983; Durando, et al. 2000; Oliveira, et al. 2012), and is composed of species that have been intensively studied for decades, as is the case of the species of the *D. mojavensis* and *D. buzzatii* clusters (Byrne 1999; Etges 2002; Etges, et al. 2006; Manfrin and Sene 2006; Etges, et al. 2007). Using the comparative approach in a hypothesis testing framework, assessing rates of character evolution and the influence of phylogenetic affinities for mate recognition signals should help to resolve broad-scale evolutionary trends in mating signal evolution and provide some clarity into the origins of the spectacular diversity of mate communication systems we seek to understand.

ACKNOWLEDGMENTS

We thank P.R. Epifânio for technical assistance and C. H. A. S. Motta for recording the songs of *D. borborema*. F. F. Franco and A. L. H. Esguicero assisted with field collection of cactus and flies. Funding was provided by a supplement to National Science Foundation DEB-0211125 to WJE, a Dissertation Research Award from the J. William Fulbright College of Arts & Sciences, University of Arkansas to CCO, and grants from FAPESP, CNPq and USP to MHM and FMS.

ABSTRACT

Nasonia (Hymenoptera: Pteromalidae) are small haplodiploid parasitoids of flesh- and blowfly pupae that have become model organisms for speciation research. The genus consists of four closely related species that harbor species-specific *Wolbachia* bacteria that cause postmating reproductive isolation. Antibiotic curing allows for interspecific crosses and genetic exchange between species which, together with haploidy of males, facilitates genetic analysis of fitness traits. In this chapter we synthesize the current knowledge on the different prezygotic isolation factors that act in the *Nasonia* genus, and on the genetic basis of these traits. A major prezygotic isolation factor is courtship behaviour. Species differ in male courtship behaviour, and there is large variation in interspecific mate discrimination depending on species pair. We summarize data on the strength of prezygotic isolation barriers between all possible species pairs and present new data on mate discrimination in choice and no-choice experiments. In tests of reinforcement, we found no stronger female mate discrimination of *N. vitripennis* strains occurring in microsympatry with *N. giraulti* compared to that of allopatric *N. vitripennis* strains. Additionally, we present data on the significance of cuticular hydrocarbon profiles for assortative mating in males and discuss other factors that may be involved in prezygotic isolation, including pheromone communication, within-host-mating and sneaking behaviour.

INTRODUCTION

The Biological Species concept states that species are ‘groups of interbreeding natural populations that are reproductively isolated from other such groups’ (Mayr 1942). When a reproductive barrier between two populations arises, local adaptation and drift can lead to divergence of these populations, and eventually to speciation (Mayr 1963). These reproductive isolation barriers can be divided into those that act before fertilization, i.e., prezygotic isolation, and those that act after fertilization, i.e., postzygotic isolation (Dobzhansky 1935, Mallet 1998). Prezygotic isolation barriers typically manifest prior to mating, for example through temporal or geographic isolation between individuals, morphological differences between mating partners, or behavioural isolation (Kondrashov and Shpak 1998, Coyne and Orr 1998). However, post-mating prezygotic isolation can also occur, for example through incompatibilities between egg and sperm (e.g., Shaw et al. 1994).

Assortative mating, i.e., preferred mating among individuals of the same species over matings between individuals of different species, is arguably the most prevalent, or at least best studied, form of prezygotic isolation. Despite the fact that prezygotic reproductive barriers do not always lead to completely isolated species for prolonged periods of time, behavioural isolation can apparently evolve rapidly (Coyne and Orr 1997, 2004). The evolution of behavioural barriers can be studied especially well in young species complexes, where hybridization can still occur and a full barrier to gene flow has not yet been established (e.g., Coyne et al. 2002, Gow et al. 2006). A well-known, and frequently studied, behavioural barrier is female interspecific mate discrimination, in which females of a particular species show strong assortative mating. This behaviour can be strengthened by reinforcement, a process in which prezygotic isolation barriers are increased by natural selection against unfit hybrids (Dobzhansky 1940, Servedio and Noor 2003).

Despite the attention for behavioural reproductive isolation in the process of speciation, the genetic basis of traits that play a role in maintaining and/or creating prezygotic isolation is not well known (e.g., Arbuthnott 2009). We do not have good answers yet to many questions, such as whether behavioural isolation is based on few genes with large effects or many genes with small effects, whether most behavioural changes cause reproductive isolation (hence behavioural genes being speciation genes, *sensu* Orr et al. 2004) or come into being after the speciation event (hence contributing to species differences). Such knowledge is required to understand how selection and drift may cause changes in reproductive isolation between populations in the course of evolution.

In this chapter we present the results of many years of research on speciation in the parasitoid wasp genus *Nasonia* (Hymenoptera: Pteromalidae). *Nasonia* have been used extensively for research on speciation and adaptation for a couple of decades now (e.g., Werren 1983, Pultz and Leaf 2003, Leonard and Boake 2006), and their haplodiploid sex determination system makes them very well suited for genetic analyses (Beukeboom and Desplan 2003, Werren and Loehlin 2009, Werren et al. 2010). The complete genome sequences are available for all four species, making this young species complex ideal for genomic studies on complex traits (Werren et al. 2010). In this chapter, we present an overview of the knowledge on prezygotic isolation between the *Nasonia* species. We summarize previously published data, and provide new information that has been gathered by our research groups in the course of time.

***Nasonia* Wasps**

Nasonia (Hymenoptera: Pteromalidae) is a genus of 2-3 mm sized parasitoid wasps (Figure 1) that lay their eggs in pupae of various fly species, such as Protocalliphora, that occur in bird nests and on carcasses (Whiting 1967, Darling and Werren 1990). A clutch typically consists of 20-30 eggs depending on host size (Charnoy and Skinner 1984). Like all Hymenoptera, *Nasonia* has a haplodiploid mode of reproduction (Whiting 1967). Males are uniparentally produced and haploid; they develop from unfertilized eggs. Females have a mother and a father, are diploid and develop from fertilized eggs. Females store sperm after mating and can control the process of egg fertilization (Holmes 1972, Werren 1984, King and Skinner 1991). In the field, clutches typically contain mostly fertilized (female) eggs (Whiting 1967, Werren 1983), of which the developmental time is approximately 14-16 days at 25°C. Male offspring emerges first and stay at the natal patch where they mate with emerging females, that can both be their sisters and offspring of other founding parental females, if present (Whiting 1967, van den Assem et al. 1980, Leonard and Boake 2006). Females typically mate only once and disperse in search of new host patches, but they may become receptive a second time 24 hours after mating (van den Assem and Visser 1976, Grillenberger et al. 2009a). The combination of these life history traits makes *Nasonia* a prime example of local mate competition (Hamilton 1967, Werren 1980, 1983).

The *Nasonia* genus consists of four species: *N. vitripennis*, *N. giraulti*, *N. longicornis* (Darling and Werren 1990), and the recently discovered species *N. oneida* (Raychoudhury et al. 2010a). *N. vitripennis* diverged from its sister species approximately 1.0 million years ago (Campbell et al. 1993), while *N. longicornis* and *N. giraulti* diverged approximately 0.5 million years ago (Raychoudhury et al. 2010b), and *N. oneida* diverged from *N. giraulti* 0.4 million years ago (Raychoudhury et al. 2010a). *N. vitripennis* is a cosmopolitan species and occurs in sympatry with *N. giraulti* and *N. oneida* in eastern and with *N. longicornis* in western North America, respectively (Darling and Werren 1990; Raychoudhury et al. 2010a, Figure 2). *N. longicornis* is spatially isolated from *N. giraulti* and *N. oneida*, but *N. vitripennis* is the only species that occurs in true allopatry outside North America. In areas of sympatry, the opportunity for hybrid matings is potentially high because the species are morphologically very similar (Darling and Werren 1990), they can occupy the same host patch or even hatch from the same host pupa (Darling and Werren 1990, Grillenberger et al. 2009b) and they can hybridize in the laboratory. Exact frequencies of hybrid matings under natural conditions have not been investigated so far. However, there is strong postzygotic reproductive isolation between most of the species in nature due to infection with species-specific strains of *Wolbachia* bacteria that cause cytoplasmic incompatibility and hybrid breakdown (Breeuwer and Werren 1990, 1995). Such incompatibility, between egg and sperm that are infected with different *Wolbachia* strains, results in improper condensation, eventual damage and subsequent loss of the paternal chromosomes in fertilized eggs (Ryan and Saul 1968, Breeuwer and Werren 1990, Tram and Sullivan 2002). The resulting haploid embryos may either die or develop into haploid males (Breeuwer and Werren 1990, Bordenstein and Werren 1998, Bordenstein et al. 2003, Tram et al. 2006). Interspecific matings therefore usually result in all-male progenies, the haploid males being non-hybrid because of haplodiploidy, and sometimes in reduced offspring numbers. The strength of cytoplasmic incompatibility varies between species pairs, and is generally proportional to their divergence times. The *Wolbachia* strains of *N. vitripennis* induce complete incompatibilities with those of all three other species, *N. giraulti* and *N.*

longicornis strains are partially incompatible (Breeuwer and Werren 1990, Bordenstein et al. 2001), but the *Wolbachia* strains from *N. oneida* are fully compatible with those of *N. giraulti* and partially compatible with those of *N. longicornis* (see Raychoudhury et al. 2010a and Figure 4 for details). Antibiotic curing from the *Wolbachia* bacteria allows for heterospecific crosses in the laboratory that yield viable and (partially) fertile F1 females and F2 males, despite other pre- and postzygotic barriers that are present between the different species pairs at varying degrees.

Apart from cytoplasmic incompatibilities reducing the number of hybrid offspring, F2 hybrid males, between *N. vitripennis* and both *N. giraulti* and *N. longicornis*, suffer from strong postzygotic hybrid breakdown (Breeuwer and Werren 1995, Gadau et al. 1999, Niehuis et al. 2008, Clark et al. 2010, Koevoets et al. 2012) Together, through these postzygotic isolation mechanisms a substantial fitness disadvantage can be expected from females who permit courtship from and copulations with heterospecific males. Similarly, from the male perspective, investment in interspecific copulations means a complete absence of mating success in terms of paternal genetic contribution to the offspring (Bordenstein and Werren 2007). Thus, selection pressure towards mate discrimination and assortative mating is a likely consequence, favoring the ability to discriminate conspecific from heterospecific mating partners (Butlin 1987). In this chapter we present the current knowledge on prezygotic isolation mechanisms in the *Nasonia* genus and consider whether the observed species differences could have evolved in response to maladaptive hybridization.

Figure 1. *Nasonia vitripennis* female, parasitizing a host, and male (top left corner). Photos by Peter Koomen.

Figure 2. Geographical distribution of the four *Nasonia* species. *N. oneida* was recently discovered, and has as yet only been found in the region of Ithaca (NY). *N. vitripennis* is a cosmopolitan species.

COURTSHIP AND MATING BEHAVIOUR

The *Nasonia* species differ in male courtship behaviour and can be discerned by their species-specific alterations of a common courtship pattern (van den Assem and Werren 1994, Drapeau and Werren 1999). This difference alone is not sufficient to prevent interspecific matings. In fact, it is still not well known to what extent these differences in male courtship behaviour are perceived by females to affect their receptivity. Moreover, it is unclear whether male courtship behaviour has mostly been shaped by intraspecific sexual selection as suggested by Barrass (1976) and Jachmann and van den Assem (1996), or has also been modulated by interspecific interactions. In *Nasonia*, female reproductive behaviour appears to induce a stronger isolation than male behaviour does. In addition to information obtained from male courtship behaviour, females might discriminate against males of other species using species-specific differences in sex pheromones, aphrodisiacs and sound (Ruther et al. 2009, Robertson et al. 2010, Niehuis et al. 2011).

Nasonia has been extensively used for behavioural studies for several decades (Barrass 1960, van den Assem and Visser 1976; van den Assem 1986, Jachmann and van den Assem 1993; van den Assem and Werren 1994), including some studies of the underlying genetics of behaviour (Beukeboom and van den Assem 2001, 2002, Velthuis et al. 2005). In this chapter, female interspecific mate discriminating behaviour is considered to be the main prezygotic isolation mechanism that separates the *Nasonia* species. This behaviour, in which females of a species are reluctant to mate with heterospecific males, can be influenced by a number of different cues that are embedded in the mating sequence. However, research of the previous years focused almost solely on male courtship behaviour and female response. In laboratory observations, the start of a mating sequence is marked by the latency time. This is the time it takes the male and female to approach each other, and defined as the time period between the moment of introducing the two partners to the mating arena and the moment that the male mounts the female and takes up the courtship position on top of the female. Following some

evidence from van den Assem et al. (1980), Ruther et al. (2007) showed that *Nasonia vitripennis* males release a sex pheromone from their abdomen to attract females. This pheromone can be considered as a cue for the female, and might determine the duration of the latency time.

After the male has mounted the female, the male courtship behaviour of *Nasonia* males is composed of stereotypic movements, which differ quantitatively and qualitatively between the species (see for details van den Assem and Werren 1994, Drapeau and Werren 1999, Beukeboom and van den Assem 2001 and Figure 3). Typically, courting males take up an invariable courtship position on top of the female, with the front legs placed on the female's head (Barrass 1960). A conspicuous feature of the courtship performance is head nodding: repeated bouts of nods that are separated by short pauses (Barrass 1960). The first head nod in a bout coincides with mouthpart extrusions, which is probably linked to the release of a pheromone (van den Assem et al. 1980). This pheromone is believed to be involved in the process of induction of female receptivity (van den Assem et al. 1980), but its chemical composition has to date not been elucidated. If indeed the first head nod in a series coincides with pheromone release head nod frequency has at least a modulating role in the mating behaviour sequence. Therefore, head nodding behaviour and pheromone release are considered additional cues for the female to assess the male species.

A third factor that may play a role in *Nasonia* mate choice is male song. Male song, created by wing vibrations, is an important part of male courtship behaviour in *Drosophila*, where it has been studied in many species (e.g., Kyriacou and Hall 1982, Ritchie and Gleason 1995, Li et al. 2012). Male *Nasonia* wasps also vibrate their wings while performing head-nods, and these songs are also seen as part of their courtship behaviour. These vibrations can be recorded (van den Assem 1986, Diao et al. unpublished) and potentially differ between the four species, for example by reflecting the differences in male wing lengths between the species. However, the functional significance of song patterns in the *Nasonia* mating sequence remains to be analysed and requires additional manipulative experimentation.

After assessing the above mentioned cues, females typically show their willingness to copulate, and thus acceptance, during the first head nod of a series by sweeping their antennae downwards and opening their genital orifice by raising their abdomen. Males immediately back up and copulation follows (Barrass 1960). Copulations last for 12-14 seconds and do not seem to differ between the species. Immediately after copulation the male performs a sequence of postcopulatory courtship before dismounting. If females do not become receptive, as manifested by their unwillingness to adopt the copulatory position, males will eventually terminate their courtship performance and dismount. When presented with an already mated female, males of the four *Nasonia* species differ in the number of head nod cycles they perform until dismounting. For example, *N. vitripennis* typically terminates courtship faster (after 7-8 cycles) than *N. longicornis* (after 12-13 cycles) (Beukeboom and van den Assem 2001). In addition, the number of cycles is affected by the number of courtship bouts that the male has performed in the recent past (Jachmann and van den Assem 1996).

The degree of prezygotic isolation between the *Nasonia* species is likely determined by an interaction between male courtship behaviour, chemical communication, male song on the one hand, and the females' response to these traits, in terms of interspecific mate discrimination behaviour on the other. In contrast to males, which mate multiple times, females typically mate only once in nature, therefore selection for conspecific mating is expected to be stronger in females (van den Assem 1986, Burton-Chellew et al. 2007, Grillenberger et al. 2008).

Figure 3. Schematic representation of the courtship pattern of *Nasonia*. Pictures by Michael Clark.

Figure 4. General patterns of intraspecific and interspecific female mate discrimination in the four *Nasonia* species. For each species pair, the number of females is shown that rejected or accepted the male partner. Observations are performed using a variety of strains; the number of strains used per species is indicated below the female species name. Occurrence and strength of cytoplasmic incompatibilities, induced by species-specific *Wolbachia* infections, are shown for all species pairs.

PATTERNS OF MATE DISCRIMINATION: NO CHOICE EXPERIMENTS

Tests for mate discrimination usually consist of behavioural observation trials (or mating trials) in which successful copulations are scored as present or absent. Female mate discrimination is then defined as the percentage of females that rejected their mate. Mating trials in *Nasonia* are typically performed as no-choice experiments by placing one virgin male

and one virgin female of standardized age (1 or 2 days old) in a small arena and observing them for 5-30 minutes. In intraspecific setups, the vast majority (>96%, Figure 4) of mating pairs result in copulations within the observation time frame. True choice experiments with two or more males or females are hard to perform as it remains difficult to interpret the interaction between interspecific male-male competition and female choice. The main reason for this is that males of the different species differ strongly in their aggressiveness, with *N. vitripennis* males being the most aggressive (Leonard and Boake 2006, this chapter). By combining a number of no-choice experiment datasets that have been collected in our laboratories over the years, a general overview can be made of female mate discrimination patterns between the four *Nasonia* species (Figure 4). In these no-choice experiments, mate discrimination is scored when a male successfully mounts and courts a female, but the female does not signal receptivity and no copulation occurs. Although significant quantitative differences are found between the studies, this does not lead to qualitative differences in the observed patterns, and therefore the results of the different studies can be combined. Furthermore, results found in our study are quite similar to data shown in Bordenstein et al. (2000). In the next section we will shortly discuss these similarities.

Strong asymmetric sexual isolation exists between the different *Nasonia* species, with *N. vitripennis* showing the highest female mate interspecific discrimination. *N. vitripennis* females have high mate discrimination against *N. giraulti* (90%) and *N. oneida* males (90%), but accept *N. longicornis* males more frequently (71% discrimination). *N. giraulti* and *N. longicornis* females show comparable heterospecific mate discrimination patterns against males of all three species: low mate discrimination against *N. vitripennis* males (20%), and slightly higher against *N. oneida* males (approximately 25%). As *N. longicornis* and *N. giraulti* do not occur in sympatry (Darling and Werren 1990), mate discrimination between these two species is expected to be low. Our results are consistent with this, *N. longicornis* females hardly discriminate against *N. giraulti* males (8%), and neither do *N. giraulti* females against *N. longicornis* males (5%). Similarly, *N. oneida* females discriminate strongly (97%) against males of the sympatric species *N. vitripennis*, but discrimination against *N. longicornis*, which is allopatric to *N. oneida*, is lower (63%). *N. giraulti* males are more often accepted by *N. oneida*, with only 25% of the females rejecting the *N. giraulti* males. This last result contradicts the prediction that mate discrimination of species that occur in sympatry is higher than allopatric species pairs. To further quantify the degree of prezygotic isolation between the four *Nasonia* species we calculated a prezygotic isolation index, using the following formula:

$$i = \frac{\text{frequency of heterospecific matings of both reciprocal crosses}}{\text{frequency of homospecific matings of both species}} = \frac{[A \times B] + [B \times A]}{[A \times A] + [B \times B]} \quad (1)$$

Indexes are shown in Table 1. We can infer that prezygotic isolation is strongest between *N. vitripennis* and *N. oneida*, and weakest between *N. giraulti* and *N. longicornis*, as is expected by their allopatric status. The prezygotic isolation index between *N. giraulti* and *N. oneida* is fairly low, contradicting what would be expected based on the theory of reproductive character displacement, which states that differences in behaviour (in this case displayed by mate discrimination) are stronger in sympatrically occurring species as opposed to allopatrically occurring species (Brown and Wilson 1956, Grant 1972).

Table 1. Patterns of prezygotic isolation between the four *Nasonia* species, as indicated by prezygotic isolation index (i). As this index is designed for heterospecific matings, no values can be calculated for intraspecific crosses

species	<i>N. vitripennis</i>	<i>N. longicornis</i>	<i>N. giraulti</i>	<i>N. oneida</i>
<i>N. vitripennis</i>				
<i>N. longicornis</i>	0.445			
<i>N. giraulti</i>	0.553	0.040		
<i>N. oneida</i>	0.932	0.434	0.204	

0 = no isolation.

1 = complete isolation.

Interestingly, asymmetric patterns exist in mate discrimination. This means that for two species A and B, species A could strongly discriminate against species B, but species B might not necessarily show such strong discrimination against species A. To indicate asymmetric patterns of mate discrimination, the prezygotic isolation index was slightly adjusted:

$$i' = \frac{\text{frequency of heterospecific matings with female of species A}}{\text{frequency of homospecific matings of species A}} \quad (2)$$

Indexes for asymmetrical isolation are shown in Table 2. From these indexes it can be concluded that strong asymmetrical patterns of prezygotic isolations exist for crosses with *N. vitripennis* (except for *N. vitripennis* and *N. oneida*), reflecting the strong discriminatory behaviour of *N. vitripennis* females. Asymmetry was also found in the *N. longicornis* and *N. oneida* species pair, as a result of strong mate discrimination of *N. oneida* females.

These results show that prezygotic isolation in the *Nasonia* complex is incomplete and confirm previous results (van den Assem and Werren 1994, Bordenstein et al. 2000). Additionally, the data are partially reflective of the geographical distribution and sympatry of the four *Nasonia* species, but are not entirely explained by these factors.

Table 2. Patterns of asymmetrical prezygotic isolation between the four *Nasonia* species, as indicated by the asymmetrical prezygotic isolation index (i'). The upper right section and lower left section can be compared to show asymmetries in isolation

		Male species			
		<i>N. vitripennis</i>	<i>N. longicornis</i>	<i>N. giraulti</i>	<i>N. oneida</i>
Female species	<i>N. vitripennis</i>		0.701	0.907	0.899
	<i>N. longicornis</i>	0.185		0.059	0.262

Table 3. Variation between strains of the same species for interspecific mate discrimination (IMD) against *N. vitripennis* and *N. giraulti* males

Female species	Male species	Total IMD	1	2	3	4	5	6	7	8	9	10
<i>N. vitripennis</i>	<i>N. giraulti</i>	91±1% (n=664)	97±2% (n=46)	89±3% (n=115)	100% (n=90)	93±4% (n=44)	100% (n=19)	98±2% (n=43)	82±4% (n=95)	92±4% (n=39)	73±5% (n=70)	96±2% (n=103)
<i>N. giraulti</i>	<i>N. vitripennis</i>	21±2% (n=295)	47±8% (n=36)	15±4% (n=68)	31±7% (n=48)	26±5% (n=74)	3±2% (n=69)					

Given is the sample size, percentage and standard error of females that discriminate against males of the other species. *N. vitripennis* strains used are 1-Sal12, 2-Sal8, 3-ITH4c, 4-ITH3F from Ithaca, New York; 5-LabII standard lab strain from Leiden, The Netherlands; 6-HV2004, 7-HV2003, 8-HVRx from The Netherlands; 9-ITA2 from Italy and 10-Russia Bait from Russia. *N. giraulti* strains used are 1-RV2 standard lab strain from New York; 2-GMix mixed population from 5 *N. giraulti* strains originating from Virginia, Pennsylvania and New York; 3-NGVA1 and 4-NGVA2 from Virginia; 5-NGPA from Pennsylvania.

In addition to these differences between the four *Nasonia* species, intraspecific differences in mating behaviour are common, and occasionally a *N. vitripennis* strain has been collected in Europe (e.g., ITA2 from Italy) that shows low interspecific mate discrimination. Also *N. giraulti* strains show large variations for interspecific mate discrimination against *N. vitripennis* (Table 3). Intraspecific crossings, however, are almost always successful regardless of the tested strains. For example, crosses between different *N. vitripennis* strains result in copulation in almost 100% of the cases. This has been tested by observing a total of 600 matings pairs of 20 strain combinations collected along a latitudinal gradient of 20 degrees (latitude 42-62) within Europe. Mate acceptance was high (97%) between all strain combinations (data not shown), indicating that there is no isolation between the strains. Only significant differences in latency time were found (GLM, $df=19$, $\chi^2=54.38$, $p < 0.0001$). These results point at absence of intraspecific isolation within *N. vitripennis* strains. This is consistent with the observation that European and North-American *N. vitripennis* strains cross readily in the laboratory (see also the section on reinforcement below).

CHOICE EXPERIMENTS: IMPLICATIONS OF MALE-MALE COMPETITION

In an experimental set-up in which we aimed to investigate female mate discrimination in *N. vitripennis*, when given a choice between a conspecific male and a *N. giraulti* male, we noticed a number of issues relating to male-male competition. A total of 200 *N. vitripennis* females were given a choice between a heterospecific and conspecific male. The conspecific *N. vitripennis* male was significantly more often the first male to court the *N. vitripennis* female ($\chi^2=39.8$, $df=3$, $p < 0.0001$). This shows that, when paired with a *N. vitripennis* female, *N. vitripennis* males almost always win the male-male competition with *N. giraulti* in terms of first mounting the female (Table 4). This is consistent with *N. vitripennis* males being more aggressive (Leonard and Boake 2006). Additionally, sneaking behaviour (van den Assem 1986) was observed in *N. vitripennis* males for 35% of the observed crosses, i.e., while the *N. giraulti* male performed courtship behaviour to induce female receptivity, the *N. vitripennis* male sits on the female's abdomen and copulates with her upon becoming receptive. In a choice experiment with *N. giraulti* females paired with both a *N. vitripennis* and a conspecific male, *N. vitripennis* males showed sneaking behaviour in 54% of the observed crosses. In contrast, *N. giraulti* males never performed sneaking behaviour, in choice experiments with either a *N. vitripennis* or *N. giraulti* female (see Table 4). Sneaking behaviour appears to be a strategy that has evolved in response to strong male-male competition within *N. vitripennis*, which is supported by observations of sneaking attempts in intraspecific crosses (data not shown). As male-male competition and differences in aggression (for example sneaking attempts), between the *Nasonia* males of the different species, likely interact with female choice, it is ambiguous to make conclusions on female interspecific mate discrimination using this experimental set-up. Testing female mate discrimination in a true choice experiment will require an experimental set-up that does not allow for male-male interactions.

Table 4. Mating behaviour differences in choice mating trials between *N. vitripennis* and *N. giraulti*

Species	First mounting of <i>N. vitripennis</i> ♂ in heterospecific contests. Cross with <i>N. vitripennis</i> ♀	Male sneaking behaviour in heterospecific contests. Cross with <i>N. vitripennis</i> ♀	Male sneaking behaviour in heterospecific contests. Cross with <i>N. giraulti</i> ♀
<i>N. vitripennis</i>	72% (N=200)	35% (N=192)	54% (N=94)
<i>N. giraulti</i>	58% (N=100)	0% (N=192)	0% (N=94)

GENETICS OF MATE DISCRIMINATION

The genetics of male reproductive behaviour in *Nasonia* has been investigated using interspecific crosses (Beukeboom and van den Assen 2001; Beukeboom et al., in prep). These studies reveal a complex regulation with multiple QTL for different courtship components and abundant epistatic interactions between different loci. The genetic architecture of female mating behaviour has not been studied to the same extent (but see Velthuis et al. 2005). Recently, Giesbers et al. (in prep) analysed the genetic basis of female interspecific mate discrimination (IMD) in *N. vitripennis* against *N. giraulti* males using artificial selection. They found a fast and significant response to selection resulting in a 35% decrease in mate discrimination within four generations of selection. The cumulative heritability of IMD in the artificial selection experiment was $h^2=0.29$, which shows the existence of substantial genetic variation for interspecific mate discrimination in *N. vitripennis*. Although more detailed genetic studies are required, these studies indicate that the *Nasonia* system is very well suited for investigating the genetic basis of female mate discrimination. Such studies can particularly be useful for testing the theoretically predicted genetic linkage between male signal and female choice traits, as well as for investigating the genetic basis of intraspecific versus interspecific mate choice.

OTHER TRAITS INVOLVED IN PREZYGOTIC ISOLATION

Another interesting prezygotic isolation inducing behaviour that has only been found in a few parasitic Hymenoptera species (da Costa Lima 1928, Suzuki and Hiehata 1985, Drapeau and Werren 1999) is within-host-mating, in which males and females mate inside the host before emergence. The *Nasonia* species differ in their preference for within-host-mating (Drapeau and Werren, 1999, Giesbers et al. in prep, this chapter). For our experiments, within-host-mating was scored by collecting all females from inside the host, at the moment when the first female has emerged from the host. Females that have mated inside the host will produce daughters and sons, while unmated females will only produce sons. Our results confirm earlier work by Drapeau and Werren (1999): *N. giraulti* has a high preference for within-host-mating, while *N. vitripennis* almost always mates outside the host (Figure 5). *N. longicornis* and *N. oneida* show low levels of within-host-mating. Drapeau and Werren (1999) already suggested that within-host-mating might have evolved in *N. giraulti* to avoid interspecific hybridization. As a consequence of within-host-mating, *N. giraulti* females will only encounter *N. vitripennis*

males after having mated conspecifically within the host. As re-mating rates in natural populations of at least *N. vitripennis* are very low (van den Assem et al. 1980, van den Assem and Jachmann, 1999, Grillenberger et al. 2009b), this would produce a strong barrier against interspecific mating. Additionally, it might explain our observation that *N. giraulti* females discriminate less against *N. vitripennis* males than *N. vitripennis* females discriminate against *N. giraulti* males. Our results are generally consistent with the prediction that the rate of within-host-mating is negatively correlated with the degree of interspecific mate discrimination. It remains to be seen if within-host-mating is a male or female mediated trait, or the result of an interaction between both sexes.

Figure 5. Interspecific differences in within-host-mating. For all four *Nasonia* species, the proportion of females is shown that mated either inside or outside the host. Observations are performed using a variety of strains; the number of strains used per species is indicated below the female species name. Values in the pie slices indicate the number of females.

In a study into the possible role of sexual conflict, Geuverink et al. (2009) compared copulation durations of conspecific and heterospecific crosses to test for possible mating incompatibilities (e.g., morphological or behavioural) between lines of *N. vitripennis* and *N.*

longicornis that were cured from their *Wolbachia* infection. In both species, heterospecific crosses did not differ in duration from conspecific crosses which suggests that sperm transfer is not mitigated in heterospecific crosses. This was further substantiated by occurrence of sperm in the spermatheca of heterospecifically mated females immediately after copulation. Moreover, the results indicated that the speed at which sperm is transferred and the amount of transferred sperm did not differ much between conspecific and heterospecific crosses. Furthermore, the survival of sperm in the course of time was not affected either, as females that had their reproductive period delayed by denying them access to hosts for the first ten days of their life, still appeared to have sperm in good condition in their spermatheca, regardless of whether they were heterospecifically or conspecifically mated. These data indicate that post-mating incompatibilities between heterospecific sperm and the spermatheca environment appear to play no role in *Nasonia*, at least between the two tested species *N. vitripennis* and *N. longicornis*.

Geuverink et al. (2009) used crosses between *N. vitripennis* and *N. giraulti* to determine whether female acceptance is influenced by the species of the first male partner. A clear effect of male species on female re-mating rate was found, both *N. vitripennis* and *N. giraulti* females mated more frequently after having first mated a heterospecific male. However, this increase was only significant for *N. giraulti* females, which may in part be due to the higher conspecific re-mating rate of *N. vitripennis* females under lab conditions. This shows that heterospecific males are less efficient in decreasing female receptivity. At present it is not possible to differentiate between the mechanisms that could reduce receptivity, such as differences in male postcopulatory behaviour or physiological effects of sperm in the reproductive tract of the female. Interestingly, *N. giraulti* males have longer post-copulatory courtship than *N. vitripennis* males, which may reduce the re-mating rate of *giraulti* mated females.

REINFORCEMENT

Whether interspecific mating can lead to reinforcement of premating behaviour is still controversial, even though there is both theoretical support (e.g., Butlin 1987, Liou and Price 1994, Servedio and Noor 2003) and empirical evidence for its role in premating isolation (e.g., Blair 1955, Noor 1995, Saetre et al. 1997, Rundle and Schluter 1998, Jaenike et al. 2006). A prediction of the reinforcement hypothesis is that sympatric populations will have higher levels of mate discrimination than allopatric populations of the same taxa (Jaenike et al. 2006). We compared female mate discrimination of *N. vitripennis* strains occurring in microsympatry with *N. giraulti* (from North America) with that of allopatric strains (from Europe). The opposite comparison, involving mate discrimination of allopatric *N. giraulti* females towards *N. vitripennis* males, is not possible, because *N. giraulti* has to date not been found in areas where *N. vitripennis* is absent.

We used a no-choice experiment in which females of four allopatric (European) and four sympatric (North American) *N. vitripennis* strains were tested against males of an *N. giraulti* strain (North American) using crosses to males of their own strain as control. Females of the allopatric *N. vitripennis* strains accepted *N. giraulti* males in 2-26% of cases compared to 0-13% of cases of sympatric strains (Figure 6), which is not significantly different (GLMM: df=1, Chi=1.36, p=0.2441). The control experiments of the conspecific design showed an invariably

high mating rate (near 100%) for both *N. vitripennis* and *N. giraulti*. Although female mate acceptance did not differ between the allopatric and sympatric strains of *N. vitripennis*, a trend exists towards longer duration of courtship bouts that *N. giraulti* males needed to induce receptivity in sympatric females compared to allopatric females (GLMM: $df=1$, $\chi^2=3.47$, $p=0.063$, Figure 7, only courtship bouts that resulted in receptive females were taken into account). This is in line with the prediction of the reinforcement theory. In nature, males may give up courting sooner and pursue another female, since more than one mating partner may be present on a patch. For latency time no significant difference between allopatric and sympatric females was found (GLMM: $df=1$, $\chi^2=2.87$, $p=0.0902$, Figure 7), although there is a trend towards higher latency time in the sympatric design, in line with the reinforcement hypothesis.

Figure 6. Proportion of *N. vitripennis* females that mated in heterospecific (*N. giraulti* male, left panel) and conspecific (*N. vitripennis* male, right panel) no-choice experiments. Females from sympatric strains are indicated by grey bars; females from allopatric strains by black bars. The right most white bar represents the proportion mating females in a conspecific no-choice experiment with *N. giraulti* males. Sample sizes are shown between brackets on the x-axis. GLMM indicated no significant difference in proportion mating females between allopatric and sympatric strains in both heterospecific and conspecific no-choice experiments ($\chi^2=4.56$, $df=2$, $p=0.102$, significance indicated by capital letters in the plot).

Another prediction of the reinforcement hypothesis is that females that occur sympatrically will evolve reproductive character displacement resulting in stronger discrimination against males of their own species from allopatric populations, as for example found by Jaenike et al. (2006) in two *Drosophila* species. We found no evidence supporting this prediction in our study as all conspecific designs, including those between females and males of different continents yielded high acceptance rates (over 96% successful matings in both directions). Furthermore, there was no significant difference in courtship duration within the conspecific design between

allopatric and sympatric strains (GLMM: $df=1$, $\chi^2=0.44$, $p=0.507$, Figure 7). This indicates that the observed elevated courtship duration of the sympatric heterospecific design is not a strain effect, but may reflect early reinforcement. We conclude that reinforcement has at most slightly strengthened prezygotic isolation between these two species through courtship duration but not female mate acceptance.

Figure 7. Latency time and courtship duration of five different designs in no-choice experiments. The two box and whiskers in the left panel show results of the heterospecific design with *N. vitripennis* (Vit) females from allopatric (Allo) and sympatric (Sym) strains. The three box and whiskers in the right panel refer to conspecific controls of both species. The two *N. giraulti* (Gir 1 and Gir 2) strains are pooled. There is no difference in latency time between allopatric (Vit_{Allo} x Gir) and sympatric (Vit_{Sym} x Gir) heterospecific design. All conspecific designs differed significantly from the heterospecific designs. A pairwise comparison of courtship duration was significant for the heterospecific design, but not for the conspecific control design. Significance at $\alpha=0.05$ level is indicated by capital letters in the plot. The top and bottom of the boxes give the 25th and 75th percentile; the line in the middle of the box is the median. The ends of the whiskers represent the 2nd and 98th percentile. Outliers are indicated by open circles. Sample sizes are given at the bottom of the plot. Statistical details are given in the text.

Bordenstein et al. (2000) found that *N. longicornis* females discriminate stronger against *N. vitripennis* males than *vice versa*, which they believe is due to an increased exposure to hybridization of *N. longicornis* because its distribution range is embedded within that of *N. vitripennis* (see Figure 2). In addition, *N. vitripennis* is a generalist parasitoid and appears to have higher population densities than *N. longicornis*, which likely results in higher incidences of microsympatry. These authors also found some evidence for reinforcement within *N. vitripennis* as one allopatric strain of Minnesota showed higher receptivity to *N. longicornis* (88% mating) than sympatric females (40-66% mating). As reinforcement in *N. giraulti* may have acted upon the evolution of within-host-mating, the strongest effect of reinforcement on female interspecific mate discrimination may actually be found in *N. oneida*. This species was only recognized as a separate species because of its strong mating discrimination against its sympatric congeners *N. vitripennis* and *N. giraulti*. No investigations of reinforcement have been performed with *N. oneida* as of yet.

One possible reason for not finding strong evidence of reinforcement in *N. vitripennis* is that not enough time has passed since its sympatry was established. Following results of van Opijnen et al. (2005), Raychoudhury et al. (2010b) found evidence from molecular studies that current *N. vitripennis* populations in North America result from a recent (re) immigration event from Europe. Thus, the courtship behaviour of *N. vitripennis* might not yet have completely adapted to encounters with *N. giraulti*. However, Giesbers et al. (in prep) have shown that interspecific mate discrimination of *N. giraulti* can decrease in response to artificial selection within a few generations. Other studies have also shown that traits that are important for mating success, such as courtship song in *D. melanogaster*, have relatively high heritability (Hedrick 1988, Ritchie and Kyriacou 1996). The temporal aspects of selection processes involving mate discrimination may differ considerably between laboratory settings and natural conditions. This requires further investigation of the behavioural interactions in microsympatric *Nasonia* populations. Finally, reinforcement of prezygotic isolation may actually have acted on different aspects of the mating behaviour in *Nasonia* than female mate discrimination, such as within-host-mating (Drapeau and Werren 1999) or chemical communication (see below).

In conclusion, *Nasonia vitripennis* strains that occur in sympatry with *N. giraulti* seem to require longer courtship but otherwise do not show a strong increase in female mate discrimination against *N. giraulti* males. Reinforcement may rather have acted on other aspects of the mating system in *Nasonia*, e.g., within-host-mating. The high aggression of *N. vitripennis* males, the tendency to be the first to mount the female in interspecific contests and the sneaking behaviour of *N. vitripennis* males potentially make heterospecific matings between *N. vitripennis* females and *N. giraulti* males rare in nature.

CHEMICAL COMMUNICATION AND THEIR ROLE IN SPECIES DISCRIMINATION

Insects in general have exploited chemical signaling as their primary mode of communication (Greenfield 2002). Two main types of chemical cues and signals are commonly differentiated: long-range and close-range (Thornhill and Alcock 1983, Blomquist and Vogt 2003, Guarino et al. 2008). Concerning the latter type, cuticular hydrocarbons (CHC) are particularly common as close-range cues in a wide variety of insect communication systems

(Blomquist and Bagnères 2010). CHC are the prevalent fraction of the lipid layer on the outer segment of the insect cuticle (Lockey 1985, Howard and Blomquist 2005), and one of their main functions is the prevention of desiccation (Hadley 1981). As for their role in insect communication, CHC have been shown to function as both major sexual (Simmons et al. 2003; Peterson et al. 2007; Oppelt et al. 2009) and interspecific recognition cues (Bagnères et al. 1991, Takahashi and Gassa 1995, Singer 1998). CHC have been exceptionally well studied in the genus *Drosophila* with respect to species-specific CHC variation and CHC-based mate and species discrimination (Buckley et al. 1997, Ferveur 1997, 2005). Concerning CHC studies in *Nasonia*, Carlson et al. (1999) were the first to investigate the CHC profile of *N. vitripennis* and found clear sex-specific differences between adult males and females. Furthermore, Steiner et al. (2006) found experimental evidence that female CHC profiles function as sex pheromones in *N. vitripennis*, initiating courtship behaviour in conspecific males. A comparative CHC study between two *Nasonia* species was done by Raychoudhury et al. (2010a), who established that CHC profiles were divergent enough to separate *N. oneida* from its most closely related sister species, *N. giraulti*, as well as distinguish between their sexes.

Buellesbach et al. (in prep) extended the CHC profile comparison and analyzed qualitative and quantitative CHC differences between all four *Nasonia* species, and the respective sexes in each species. In this study, CHC were found to be sufficiently divergent to unambiguously separate the *Nasonia* genus according to sex and species (Buellesbach et al. submitted). Sex-specificity constitutes a general pre-requisite for CHC to function as cues in sexual communication, while species-specificity hints at their potential role in premating isolation. Pursuing this lead further, Buellesbach et al. (in prep) also performed behavioural assays focussing on the species-specificity of female CHC as mating cues. Female CHC were found to function as species-specific sexual cues for the males in most, but not all, *Nasonia* species.

We performed additional assays presented here to test for the significance of species-specific differences in female CHC profiles for assortative mating mediated by the males. In these assays, freeze-killed females were used as dummies to minimize other cues apart from CHC and those dummies were presented to con- and heterospecific males. We tested whether the males initiated courtship behaviour or not (Figure 8) and whether subsequent copulation attempts took place (Figure 9). The conspecific pairing was used as a reference for the heterospecific pairings. As a control, we assessed male courtship and copulation behaviour on freeze-killed female dummies from which the CHCs had been removed. No courtship or copulation attempts were initiated on these CHC-deprived female dummies at all (data not shown). This clearly hints at the significance of female CHC as sexual cues for males to initiate courtship and/or copulation attempts in *Nasonia*. Concerning courtship behaviour, a striking pattern of discrimination against heterospecific females most likely based on their CHC profile can be seen in *N. oneida* males, who court conspecific female dummies significantly more than all investigated heterospecific female dummies (Figure 8). In contrast, *N. vitripennis* did not discriminate con- from heterospecific female dummies at all in courting (Figure 8). *N. longicornis* only showed pronounced discriminatory behaviour regarding the initiation of courtship against *N. oneida*. Unexpectedly, *N. giraulti* males were apparently more attracted to heterospecific female *N. vitripennis* CHC profiles than to their own conspecific female CHC profile when considering their courtship attempts (Figure 9). One possible explanation for this is that their habit of within-host-mating has not resulted in any differentiation in chemical recognition.

Giesbers et al.

Figure 8. Courtship attempts of males from representative strains of all four *Nasonia* species towards conspecific and heterospecific female dummies in all 16 possible combinations. The number of courtship attempts in the respective conspecific combination was used as a reference against which the numbers of courtship attempts in the heterospecific combinations were tested for each respective male strain. Absolute numbers of courtship attempts for each male strain were tested with Bonferroni-corrected Fisher's exact tests, significant differences ($p < 0.0167$) are indicated by different letters. 20 Trials were conducted in each combination. Strains used are: *N. longicornis* (IV7R2), *N. vitripennis* (NY07/18), *N. giraulti* (NGVA II), *N. oneida* (NONY 11/36).

These differences in attraction were even more pronounced when regarding the copulation attempts (Figure 9). *N. oneida* and *N. vitripennis* generally show the same pattern for copulation attempts as for courtship attempts (see Figure 8) with a pronounced discrimination in the latter and no discrimination at all against heterospecific female dummies in the former case, respectively. *N. longicornis* males show no significant differences in number of copulation attempts against heterospecific vs. conspecific female dummies, although a trend towards more copulation attempts with conspecific female dummies is apparent (see Figure 9). *N. giraulti* males constitute the most curious case, since they did not attempt to copulate with the freeze-killed female dummies at all, independent of whether they were con- or heterospecific (Figure 9). This indicates that female CHC profiles are not sufficient as sexual cues for *N. giraulti* males to initiate copulation.

Overall, our experiments indicate that CHC profiles are important as sexual cues for males of all investigated *Nasonia* species. However, their species-specificity in initiating both courtship and copulation attempts by the males greatly varies according to the investigated species pairs, from clear male discriminatory behaviour against heterospecific female profiles (as displayed in *N. oneida*) to none at all (as displayed in *N. vitripennis*). *N. giraulti* males apparently require additional cues to discriminate con- from heterospecific females for both initiating courtship and copulation attempts on female dummies.

Giesbers et al.

Figure 9. Copulation attempts of males from representative strains of all four *Nasonia* species towards conspecific and heterospecific female dummies in all 16 possible combinations. The number of copulation attempts in the respective conspecific combination was used as a reference against which the numbers of copulation attempts in the heterospecific combinations were tested for each respective male strain. Absolute numbers of copulation attempts for each male strain were tested with Bonferroni-corrected Fisher's exact tests, significant differences ($p < 0.0167$) are indicated by different letters. 20 Trials were conducted in each combination. Strains used are: *N. longicornis* (IV7R2), *N. vitripennis* (NY07/18), *N. giraulti* (NGVA II), *N. oneida* (NONY 11/36).

In conclusion, clear indications were found for a role of female CHC profiles in *Nasonia* as sexual cues potentially involved in prezygotic isolation, but further study is needed to shed more light on both the exact mechanism of female-mediated CHC signalling as well as the particular CHC compounds functioning as the major cues for the males. Taking a different angle to investigate the basis for species-specific CHC variation in *Nasonia*, Niehuis et al. (2011) investigated the genetic background of CHC differences between *N. vitripennis* and *N. giraulti*. Using hybrid males and taking advantage of their haploidy, they found a large number of QTL (>100) governing species-specific CHC variation, distributed over all five chromosomes. The results revealed interesting associations to orthologous genes known to be involved in CHC biosynthesis in *Drosophila* as well as QTL hinting at hitherto unknown genes potentially involved in the biosynthesis of CHC compound classes (Niehuis et al. 2011). It will be an important next step to further analyze and unravel this unexpectedly complicated genetic architecture of CHC variation between the *Nasonia* species. This should ultimately lead to a better understanding of how CHC divergence is genetically maintained and biosynthetically governed.

Concerning non-CHC based, long-range chemical communication, Ruther et al. (2007, 2008) were the first to isolate a male specific sex pheromone from *Nasonia vitripennis*. Males

produce a mixture of (4R, 5R)- and (4R, 5S)-5-hydroxy-4-decanolide (HDL) from glands in their abdomen which they deposit by abdomen dipping to attract virgin females. The pheromone can be classified as long-range as females perceive it at distances of up to 5 centimeters and it remains attractive for up to 2 hours (Steiner and Ruther 2009). HDL is only attractive to virgin females; after copulation females immediately become insensitive to it (Ruther et al. 2007). In a later study using sperm depleted males, Ruther et al. (2009) could also show that virgin females' olfactory responses were positively correlated with pheromone dose, proving the mate assessment function of HDL.

In addition to the HDL pheromone, males also release a short range aphrodisiac from their mandibular glands, which appears to be deposited directly onto the female antennae during their headnods in the courtship sequence. Van den Assem et al. (1980) were the first to show the existence of this aphrodisiac by sealing the male mouthparts with glue, resulting in females that did not become receptive upon being courted by manipulated males. Ruther et al. (2011) used the same technique to show that virgin females do not lose their attraction to HDL if they have not received this short range aphrodisiac, further supporting its role in inducing female receptivity. However, the exact chemical composition of this aphrodisiac remains elusive as it appears to be difficult to isolate and analyse, and decades of intensive research did not get any closer to its chemical detection and characterization so far (Ruther, Schmitt and Werren, pers. comm.)

CONCLUSION

We have presented and discussed the current knowledge of prezygotic hybridization barriers in the *Nasonia* species complex. Although it is evident that the strengths of these barriers vary, depending on the species pair considered, it is much harder to determine how these differences potentially have evolved. It is likely that most differences came into being after postmating reproductive isolation was established. The reason is that species-specific infections with *Wolbachia* bacteria causing cytoplasmic incompatibility between the different species are considered as the most likely cause of the speciation events in the *Nasonia* genus (Bordenstein et al. 2001). *N. oneida* appears to be a clear example of sympatric speciation as it originated within the distribution range of *N. vitripennis* and *N. giraulti*. Some geographic differentiation in mate discrimination within species is apparent in *N. vitripennis*, although lack of such evidence from the other species may be due to a lower intensity of investigation.

A conspicuous characteristic of the *Nasonia* genus is its strong differences in degrees of prezygotic isolation between species. These differences are often asymmetric in that females of one species are either more or less discriminative against males of the other species. The degrees of premating isolation are generally consistent with the divergence time of the species. However, while *N. oneida* is genetically very similar to *N. giraulti*, females show very strong mating discrimination against *N. giraulti*, which indicates a rapid evolution of mate discrimination behaviour. Within-host-mating may constitute another mechanism to prevent interspecific matings in nature. Consistent with this notion, *N. giraulti* exhibits high levels of within-host-mating in combination with low levels of interspecific mate discrimination.

Chemical communication is likely another important factor in prezygotic isolation between the *Nasonia* species. Chemical signals have been shown to play important roles in the *Nasonia*

mating patterns. Sexual cues and/or signals act on at least three different levels during the *Nasonia* mating procedure, i.e., the male-produced long-range pheromone, female CHC and the male mouthpart aphrodisiac. There is clear evidence from behavioural assays that at least one of these chemical cues or signals are not only involved in intraspecific sexual selection, but also play a role in interspecific sexual isolation. Differences in male courtship displays, and possibly courtship song, likely play a modulating role.

Differentiation in mate choice among strains within species suggests that considerable levels of genetic variation are present in natural populations. This notion is supported by high heritability of mate discrimination behaviour and a fast response to selection in the laboratory. There is, however, as yet no strong evidence for a role of reinforcement in the *Nasonia* species complex (Bordenstein et al. 2000, this chapter). Several explanations can be proposed, such as that the species have diverged too recently for reinforcement to become established, or that other behaviours or traits may have been selected to prevent hybridization (e.g., within host mating, host choice). Although there is considerable overlap in the distribution ranges of the four species in North America, where species can even occur microsympatrically (e.g., in the same fly host), we still know little about behavioural interactions under natural conditions. Nevertheless, the tractability and genomic knowledge of the *Nasonia* genus makes it a promising system for further study of the evolution of prezygotic isolation and speciation.

Chapter 8

**WHERE TO LOOK FOR SPECIATION
GENES WHEN DIVERGENCE IS DRIVEN
BY POSTMATING, PREZYGOTIC ISOLATION**

Jeremy L. Marshall*

Department of Entomology, Kansas State University, Manhattan, KS, US

ABSTRACT

Not all genes are equally important during the process of speciation. This premise underlies a basic question in evolutionary biology – “Does divergence at any one gene, or set of genes, play a particularly important role in speciation?” The answer to this question may appear to be no for some forms of reproductive isolation, but there may indeed be ‘kinds of genes’ that routinely play a role in speciation when divergence is driven by postmating, prezygotic traits. Here, I outline the kinds of molecular pathways and interactions that underlie postmating, prezygotic phenotypes which ultimately points to the kinds of genes where we should look for species-specificity. Interestingly, it is only when we consider the entire system of interacting sex proteomes, cell structure, membrane dynamics, and physiological pathways that a picture of where species-specific interactions likely occur becomes clear. While this approach points to several kinds of pathways and gene types, a notable finding is that cell membrane receptors (like G-protein coupled receptors and receptor tyrosine kinases) that line the inside of the female reproductive tract and trigger post-copulation cell signaling should be considered the kinds of genes that routinely contribute to reproductive isolation and speciation when divergence is driven by postmating, prezygotic phenotypes.

INTRODUCTION

Sexual reproduction is widespread in animals and often involves internal insemination. This leads to the direct interaction of male sperm and ejaculate proteins with proteins from the female reproductive tract. Consequently, these interacting proteomes shape reproductive physiology and determine fertilization success – ultimately, influencing fitness.

Given that reproductive proteins play such a fundamental role in fitness, it is not surprising that they have been the focus of so much study. Over the last few decades, it has become clear that many reproductive proteins in both males and females evolve rapidly (e.g., Swanson et al. 2001, 2004; Swanson and Vacquier 2002a,b; Clark et al. 2006; Ramm et al. 2009; Dorus et al. 2010; Marshall et al. 2011). Interestingly, over the same time period, evolutionary biologists have demonstrated the importance of postmating, prezygotic phenotypes in isolating closely related species (reviewed in Howard 1999; more recent studies include Brown and Eady 2001; Simmons 2001; Marshall 2004; Geyer and Palumbi 2005; Dean and Nachman 2009; Levesque et al. 2010; Sweigart 2010). Taken together, these findings lead to the hypothesis that the rapid evolution of male and female reproductive proteins, along with their interactions, underlies much of the postmating, prezygotic reproductive isolation seen in nature (although few studies have directly tested this hypothesis; Turner and Hoekstra 2008).

As with all forms of reproductive isolation, there is a search for generalities in the processes and genetic mechanisms that underlie their function. Over the many decades of searching for such patterns, several important questions have arisen, including, “Does divergence at any one gene, or set of genes, play a particularly important role in speciation?” For postmating, prezygotic reproductive isolation, we know the genes of interest are some subset of male and female reproductive genes. But several questions remain, including which male and female reproductive genes are linked to reproductive isolation, are the important genes all the genes that have been shown to be under positive selection, and finally, are there kinds or sets of genes that are expected to routinely contribute to reproductive isolation? Empirical evidence will ultimately answer these questions; however, is there an *a priori* expectation of which reproductive genes are more likely to contribute to reproductive isolation and speciation? The objective of this article is to combine what we know about interacting sex proteomes, cell structure, membrane dynamics, and physiological pathways to predict the kinds of genes where we should look for species-specificity. In the end, these should not only be the types of genes that exhibit species-specific variation and are driven by positive selection, but that control postmating, prezygotic phenotypes which isolate closely-related species.

A SYSTEMS APPROACH TO POSTMATING, PREZYGOTIC PHENOTYPES

What System Underlies Postmating, Prezygotic Phenotypes?

The genomic and post-genomic era has provided new insights into the mechanisms underlying the evolution of reproductive isolation (e.g., Noor and Feder 2006; Kulathinal et al. 2009; Butlin 2010; Presgraves 2010). However, more than any one answer, what these studies have done is drive home the point that variation within genetic pathways underlies phenotypic variation – in essence, genes only make sense in light of the other genes they interact with

[apologies to Dobzhansky (1964) for borrowing his phrasing]. Countless transcriptomic studies have shown that differences in gene expression are associated with phenotypic variation (reviewed in Huestis and Marshall 2009) and RNAi/mutant allele studies have shown that knocking down one gene can dramatically alter patterns of gene and phenotypic expression (e.g., Finkel and Holbrook 2000; Bonaldi et al. 2008). So, if genetic pathways are important, then what does this say about how we should study the genetics of speciation?

To begin, it would seem we must first consider how genes interact. The answer to “how do genes interact” lies, in large part, in the products of genes, i.e., proteins, and more specifically protein-protein interactions. These interactions take place within, between, and outside of cells and can involve proteins from the same cell, different tissues or even different individuals (e.g., the interaction of male ejaculates and female reproductive tracts). A critical component of protein-protein interactions is posttranslational modification (e.g., phosphorylation, methylation, and glycosylation, among about 200 others; reviewed in Jensen 2006) as they can activate protein function, modify function, and even serve as master switches that turn on genetic pathways.

If protein-protein interactions and posttranslational modifications within pathways are important players in the genetics of reproductive isolation, then how would this fact influence how we think about the long-standing questions of the number, kind, and variation of genes driving the evolution of reproductive isolation? In thinking about this, we must recognize that pathways have physical structure that guides their operation (Alberts et al. 2007). Specifically, there is cell structure that dictates that molecules from other cells, tissues, or individuals must interact with or pass through the plasma membrane to effect change within the cell (Hancock 2005). This physical structure has implications for the genetics of reproductive isolation and thus, on these long-standing questions (e.g., Dorus et al. 2010).

The implications of this physical structure are particularly relevant for forms of postmating, prezygotic isolation – as much of this type of reproductive isolation boils down to the dynamics of signals and receivers (Endler and Basolo 1998; Boughman 2002; Sultan 2007). Whether it is sperm-eggs interactions or ejaculate-female reproductive tract interactions, the molecular mechanism underlying the signal-receiver system will shape the evolution of reproductive isolation. At the molecular level, these signal-receiver systems are controlled by ligands and receptors, with receptors (i.e., the receiver) occurring on the plasma membrane and ligands (i.e., the signal) being the extracellular molecules from other cells or individuals that bind to receptors and cause the activation of one or more genetic pathways (usually through phosphorylation; Hancock 2005). Given this, if we consider the question, “does divergence at any one gene, or set of genes, play a particularly important role in speciation?”, then we would predict an important role for receptor and ligand genes that activate genetic pathways when speciation is driven by postmating, prezygotic barriers. Furthermore, receptor-ligand systems also predict the number, effect size, and variation of genes that should underlie these types of postmating, prezygotic barriers – that is, such barriers should be controlled by a few genes (those of receptors and ligands) of large effect that exhibit structural variation.

Cell Signaling and Phosphorylation as Mechanisms Underlying Postmating, Prezygotic Phenotypes

The postmating, prezygotic phenotype that isolates a pair of species can occur at any point following successful copulation. Given this, the key question becomes at what point does a heterospecific ejaculate fail in the female reproductive tract? There are numerous reasons why such an ejaculate might fail, including being expelled from the female reproductive tract (e.g., Otronen and Siva-Jothy 1991), being attacked by the female immune system (Johansson et al. 2004), or not fully activating post-copulation physiologies (Neubaum and Wolfner 1999; McGraw et al. 2004; Yang et al. 2009). Indeed, ample research has shown that the ejaculate proteome of a male interacts with the reproductive-tract proteome of a female to initiate a wide range of post-copulation physiologies (e.g., Neubaum and Wolfner 1999; Ram and Wolfner 2007; Pilpel et al. 2008; Yapici et al. 2008; Yang et al. 2009; Heifetz et al. 2010; Vargas et al. 2010). Therefore, the failure of heterospecific ejaculates to fully activate post-copulation physiologies is driven by the heterospecific ejaculate not possessing the correct genotype or genotypes to interact properly with the female reproductive tract.

Within the female reproductive tract, the activation of particular post-copulation physiologies starts at the plasma membrane. Whether activator/ligand molecules are allowed to freely flow across the membrane through channels or bind to receptors on the membrane surface, the dynamics of cell physiology start at the membrane (see Hancock 2005). A critical component of this activation is cell signaling – whereby a single message can be received at the cell surface and then transferred to the rest of the cell, including the nucleus, via turning on a particular genetic pathway that “transfers” the message to the appropriate target in the cell (Alberts et al. 2007). In brief, there are three major types of transmembrane receptors that facilitate cell signaling: ion-channel-coupled receptors, G-protein coupled receptors (GPCRs), and enzyme-coupled receptors (e.g., receptor tyrosine kinases, RTKs, are receptors that directly phosphorylate their target when activated; Alberts et al. 2007). The latter two types of receptors (i.e., GPCRs and RTKs), along with a handful of “minor” receptors (e.g., integrins), are relevant to phosphorylation (see Figure 1).

The work of phosphorylation is done by kinases (depicted by the shaded objects in Figure 1), which are proteins that add one or more phosphate groups to the amino-acid side chains of a target protein. This process triggers conformational changes in the target protein that functionally turns it on or off. In short, the activation of a kinase can be viewed as turning on a master switch that either starts or stops a physiological process. For example, a specific GPCR receptor can be activated by a ligand, leading to the activation of a G-protein which can then turn on a specific kinase like GSK3 or one or more of a set of kinases like PKA, PKC, or PI3K (Figure 1). While these phosphorylation pathways occur in all cells, there is a rich history of studies investigating the role of phosphorylation in reproductive cells and physiology (e.g., Sato et al. 1998; Visconti and Kopf 1998; Muhrad and Ward 2002; Urner and Sakkas 2003; Simonet et al. 2004; Baker et al. 2006; Horner et al. 2006).

Overall, it is these male by female interactions that underlie successful phosphorylation of reproductive proteins and could diverge between species. For instance, species-specific divergence in one male-ligand — female-receptor pair could lead to dysfunctional phosphorylation of target proteins in the female reproductive tract (or a target cell outside the reproductive tract) following a heterospecific mating. In this case, the lack of proper binding of the male ligand to the female receptor would render the specific phosphorylation pathway

inactive and thus not turn on the “master switch” leading to a *necessary* physiological function. This proposed mechanism is all the more plausible when considering that transmembrane receptors like GPCRs and RTKs are often under positive selection (e.g., Nimura and Nei 2005; Salzburger et al. 2007; Steiger et al. 2009) and their evolutionary histories are replete with gene duplication events and subfunctionalization (Brody and Cravchik 2000; Harmar 2001; Bjarnadottir et al. 2006; Grassot et al. 2006) – thus increasing the likelihood that protein-protein mismatches will evolve.

Figure 1. Cell membrane receptors and kinases that could underlie postmating, prezygotic phenotypes. Receptors are in the plasma membrane and kinases (shaded gray) are inside the cell.

Using Phosphorylation Studies to Identify Ligand and Receptor Genes Underlying Postmating, Prezygotic Reproductive Isolation

In general, the study of phosphorylation patterns can be used as a tool to identify species-specific, receptor-ligand interactions that lead to postmating, prezygotic reproductive isolation. The key is to evaluate patterns of phosphorylation in the tissue or tissues where species-specific interactions might occur. The easiest example to consider is when a species-specific, receptor-ligand interaction takes place within the female reproductive tract. In this scenario, you can compare patterns of phosphorylation within the female reproductive tract between females that have successfully copulated with either a con- or heterospecific male. To do so, you would use 2D protein gels (not 2D-DIGE, i.e., two dimensional differential in-gel electrophoresis) that stain for total protein (e.g., usually fluorescently labeled green prior to running the gel) and phosphoproteins (i.e., proteins that have been phosphorylated; stained for after running the gel and usually in red for easy comparisons; e.g., Westermeyer et al. 2008). You would run one 2D gel on the reproductive tracts from conspecific copulations and a separate 2D gel on ones from

heterospecific copulations. As an added control, it is useful to run a similar 2D gel on reproductive tracts from virgin females.

Once these gels are run and stained, you can compare them to determine if patterns of phosphorylation in the female reproductive tract are different between con- and heterospecific copulations compared with the virgin-female control. If you find that particular phosphorylation only occurs after a conspecific copulation (but not following a heterospecific copulation or within a virgin female), then you can explore the link between that pattern and the postmating, prezygotic phenotype that isolates the species. To do this, you would first use MS/MS to identify the differentially phosphorylated proteins. Once these proteins have been identified you can assess the function of these proteins (via blast and literature searches) and determine if they could underlie the specific postmating, prezygotic phenotype. If so, then you can look at the peptide data from your MS/MS protein identifications to determine which amino acids were phosphorylated. You can then “blast” the sequences from the phosphorylated peptides in a database like the NetPhos 2.0 Server (www.cbs.dtu.dk/services/NetPhos/) to identify which kinase likely did the phosphorylation. Once you know the kinases involved a little literature review can point you toward the receptors that are involved.

Figure 2. The mechanisms (A, B, C, and D) and potential species-specific (1, 2, 3, 4, and 5) components of postmating, prezygotic isolation along the cell membrane of the female reproductive tract.

At this point, you will either need a fully sequenced genome or a reproductive tract EST database to screen for the candidate receptors. Indeed, even if you have a fully sequenced genome, a tissue-specific EST library is needed to identify candidate receptors, as there may be hundreds or thousands of receptors coded for in the genome with different ones being expressed in different tissues. With the candidate receptor(s) in hand, functional analyses (e.g., RNAi or knockout lines) can be used to determine if the candidate receptor influences the target postmating, prezygotic phenotype. If the receptor does influence the phenotype of interest, then you can try to identify the ligand that activates the receptor – a process that will warrant discussions with your local biochemist or cell physiologist.

Furthermore, once a receptor or receptor-ligand pair is identified, you can sequence the underlying gene to determine if there is species-specific variation and whether or not positive selection has influenced the occurrence of that variation. Also, if species-specific alleles for the receptor and ligand are identified, then functional assays can be conducted to determine if conspecific receptor-ligand pairs bind and, or function better than heterospecific pairs. In the end, if the above approach yields a female receptor that is linked to the postmating, prezygotic phenotype that isolates species, is under positive selection, controls a portion of phosphorylation that only occurs following a conspecific copulation, and interacts with the male ligand in a species-specific fashion, then a strong case can be made that the particular receptor-ligand pair contributes to reproductive isolation (and potentially speciation if the phenotype is among the only traits that isolate the focal species). Although a few “tools” like reproductive tract EST databases and the ability to do RNAi are needed for this approach, it can be conducted in almost any system, thus enabling researchers to explore the genetics of postmating, prezygotic isolation in non-model systems.

PATHWAYS LEADING TO POSTMATING, PREZYGOTIC REPRODUCTIVE ISOLATION

At its core, most postmating, prezygotic reproductive isolation must be driven by incompatible or dysfunctional interactions between the reproductive proteomes of heterospecifics. Understanding the dynamics of male-female proteome-proteome interactions and how they lead to reproductive isolation is a complex endeavor as there are hundreds, if not thousands, of ways in which such interactions could fail. My goals here are to outline some of the major mechanisms that should be considered, where species-specificity could occur, and ways in which these dynamics can be studied regardless of the organismal system.

Membrane Channels and Reproductive Isolation Caused by Protein-Protein Interactions Outside the Female Reproductive Tract

Researchers have known for some time that male reproductive proteins can leave the female reproductive tract and affect female physiology (e.g., Lung and Wolfner 1999; Gillott 2003; Lay et al. 2004). The mechanism of action in these cases can be relatively simple as the environment of the female reproductive tract is usually altered following copulation (e.g., Engelmann 1970; Gillott 2003). For example, the pH or salinity may change resulting in the

opening of cell membrane or tissue channels that allow molecules (including male reproductive proteins) in the female reproductive tract to leave and travel to other places in the female body. Given that the mechanism of passing through the female reproductive tract can be considered to be passive (or non-selective) in this case, it is reasonable to ask, “where might a species-specific interaction occur that leads to reproductive isolation?”

The answer to this question lies in understanding where these male sex molecules are going once they leave the female reproductive tract (see Figure 2, mechanism “A”). These male molecules could be targeting any number of tissues including the ovaries, oviducts, or brain. However, regardless of the target tissue, the male molecules could interact with receptors on the surface of the target tissue in a species-specific fashion (Figure 2, see the #1). A successful, conspecific interaction could then trigger cell signaling that leads to the initiation of post-copulation physiology. On the other hand, molecules from a heterospecific male would fail to activate the receptor thus not eliciting the post-copulation physiology.

Of the mechanisms discussed here, this is among the most difficult to assess experimentally. The difficulty, in this case, lies in determining which target tissue or tissues outside the female reproductive tract should be evaluated. A possible solution is to simply evaluate a wide range of tissues for differences in post-copulation phosphorylation (as outlined above). Consequently, there may be several different candidate receptors to test that require tissue-specific knockdown to evaluate their link to the postmating, prezygotic phenotype that isolates species. While this approach is certainly more time consuming, it is not overly expensive (i.e., a few thousand US dollars per receptor) and still workable for most systems.

Species-Specific, Receptor-Gated Membrane Channels

Mechanism “B” (Figure 2) assumes that a species-specific interaction between a male ejaculate molecule and a female receptor (see #2 in Figure 2) controls the opening of a membrane channel that subsequently allows non-species specific molecules to flow across the female reproductive tract membrane and eventually bind with a receptor activating a post-copulation physiology. As with mechanism “A”, identifying the interacting proteins can be difficult. For example, this mechanism could yield patterns of post-copulation phosphorylation similar to those from mechanism “A”; yet unlike mechanism “A”, a study of the receptors in the affected tissue would yield no evidence of a species-specific interaction linked to the postmating, prezygotic phenotype. Instead, a functional analysis of membrane channel receptors, especially those that are uniquely expressed in the female reproductive tract, would be a reasonable place to start. Moreover, if such a receptor were found to be linked to the postmating, prezygotic phenotype, then the next step would be to simply sequence the receptor gene to assess species-specific variation. A finding of species-specific variation, especially variation driven by positive selection, would warrant further study as a mechanism of reproductive isolation.

Species-specific, Male-female Protein Interactions within the Female Reproductive Tract

A common mechanism of species-specific interactions involves the direct interaction of male ejaculate proteins and female reproductive tract proteins (see #3 in Figure 2). These interactions could involve a wide range of proteins and peptides. For example, species-specific cleavage of a male pro-hormone by a female protease may generate the ligand that activates a membrane channel (see mechanism “B” in Figure 2) or a phosphorylation pathway (Figure 2), or passes through a membrane channel to interact with a receptor outside the female reproductive tract (mechanism “C” in Figure 2). The hormone ligand in this scenario does not have to exhibit species-specific variation, it simply has to be cleaved in a species-specific fashion. On the other hand, the pro-hormone—protease interaction does not itself have to be a species-specific interaction, as the resulting ligand could contain variation that results in species-specificity when it interacts with a receptor inside (see #2 and #5 in Figure 2) or outside the female reproductive tract (see #4 in Figure 2).

These types of male-female proteome interactions can be evaluated with comparative proteomic techniques like 2D-DIGE (e.g., Westermeier et al. 2008). With this technique, two or three samples can be compared on the same protein gel with each sample being labeled with a different fluorescent dye. So, if we compare a female reproductive tract following a conspecific copulation with one from a heterospecific copulation, then it would be possible to determine if a single or set of “new” protein spot showed up on the gel following the conspecific copulation, but not the heterospecific one – which would provide evidence for a species-specific interaction. You would also have two controls in this case with at least one of them run on the above gel as a third sample. The two controls would be (1) comparing virgin female reproductive tracts from the two species and (2) comparing male ejaculates from the two species with each control being run on a separate 2D-DIGE gel (also each species would be labeled with a different dye). The control for the above post-copulation gel would be a combined sample from one of these sex-specific controls. The power of this design is that you can separate the effects of species divergence from species-specific “processing events” that only occur after a conspecific copulation. As outlined above, these uniquely processed proteins can be identified with MS/MS and tested further. Of all the mechanisms outlined here, this is likely the easiest to conduct and can be a very powerful way to begin to explore the genetic basis of postmating, prezygotic phenotypes (see Marshall et al. 2011).

Mechanisms Triggering Phosphorylation within the Female Reproductive Tract

While the above pathways are possible, previous research points to processes such as cell signaling and phosphorylation in the female reproductive tract as being key players in initiating post-copulation physiologies. In particular, transcriptomic studies comparing the reproductive tracts from virgin females to those from mated females indicate that a large number of genes are turned on after mating (e.g., Wolfner 2002; McGraw et al. 2004, 2008; Mack et al. 2006). Based on cell structure, the activation of gene expression in female reproductive tissues post-copulation must be triggered by cell signaling – specifically through the action of male ligands

binding to transmembrane receptors in the female reproductive tract that in turn activate the phosphorylation pathways leading to gene expression (reviewed in Hancock 2005). This finding in combination with research showing that phosphorylation plays a key role in reproductive physiology (e.g., Visconti and Kopf 1998; Simonet et al. 2004; Escobar-Restrepo et al. 2007), indicates that the successful initiation of phosphorylation within the female tract is a fruitful area to search for species-specificity.

As shown in Figure 2, there are several pathways to generate species-specificity in the receptor-ligand interaction that triggers phosphorylation (see the “inside female reproductive tract” portion of mechanism “D” in Figure 2). Indeed, the ligand can come directly from the male and interact with the cell membrane receptor in a species-specific fashion (see #5 in Figure 2). However, as outlined in the “Species-specific, male-female protein interactions within the female reproductive tract” section above, the male ligand could be processed in the female reproductive tract prior to interacting with the female receptor. In this case, species-specificity could lie in the processing event or the product of the processing event. Regardless of the pathway, it is not difficult to see how heterospecific copulations could yield a ligand, or set of ligands, that fail to induce post-copulation phosphorylation and thus, results in reproductive isolation.

CONCLUSION

In all, the above is meant to paint a very particular picture about how basic biology, cell structure and function, and organismal physiology combine to reveal that certain kinds of genes are more likely than others to be involved in postmating, prezygotic reproductive isolation. While there are certainly accents or fine-scale elements that may be missing from the above picture, I hope the canvass reveals the major themes and motivates increased research on the genetics of postmating, prezygotic isolation. One brush stroke that I may not have emphasized enough is the ubiquity of this approach. We have been doing these approaches in the cricket genus *Allonemobius*, which is not a genetic model system. The proteomic and biochemical approaches outlined here, for the most part, can be used in almost any system – thus making it possible for a relatively complete picture of the genetics of postmating, prezygotic isolation to be developed if enough researchers add a brush stroke from their respective organismal system.

ACKNOWLEDGMENTS

I thank my students and colleagues, past and present, for their help in developing this approach to the genetics of postmating, prezygotic isolation. As I have stated in numerous seminars, I am not a biochemist, so I am particularly thankful for Drs. John Tomich and Brenda Oppert at Kansas State University for teaching me and guiding me through the process of comparative proteomics. The ideas for this work were developed from my research funded by NSF (DEB-0746316). This is contribution number 12-376-B from the Kansas Agricultural Experiment Station.

ABSTRACT

Speciation, the process by which one species splits into two, involves the evolution of reproductive barriers such as the sterility or inviability of hybrids between previously interbreeding populations. One of the earliest intrinsic barriers to gene flow to evolve between geographically isolated populations is the sterility of hybrids of the heterogametic sex. The Dobzhansky-Muller model describes how hybrid incompatibilities that underlie intrinsic postzygotic reproductive barriers such as hybrid sterility may evolve. A major goal in speciation research is to identify the genes that underlie hybrid incompatibilities. The identification of such genes opens the door to understanding the molecular pathways which, when tinkered by evolution within species, lead to sterility in hybrids, and promises to reveal the biological forces that drive the evolution of hybrid sterility genes. While very few hybrid sterility genes have been identified so far, the idea that the evolution of DNA-protein interfaces driven by intragenomic conflict may cause hybrid sterility is gaining wider acceptance. Here we describe how the molecular and evolutionary insights from two hybrid sterility genes – *Odysseus* and *Overdrive* – have illuminated the role of heterochromatin in the molecular basis of hybrid sterility and the role of genetic conflict as a driving force in speciation.

INTRODUCTION

In his book *"On the origin of species"*, Darwin compiled overwhelming evidence for two key phenomena. First, species adapt. Second, single species can split into two species. A combination of these two processes, according to Darwin, is able to provide a natural explanation for the amazing diversity of life. One of the great and enduring successes of Darwin lay in his explanation of the first process. Species adapt through the mechanism called "natural selection" in which genetic variation within a population is constantly subjected to selection sieves, through which alleles conferring fitter traits pass through to subsequent generations while those conferring weaker traits do not. The second process, however, vexed Darwin till the end. Speciation, the process by which one species splits into two, involves the evolution of reproductive barriers such as the sterility or inviability of hybrids between previously interbreeding populations. The question of how natural selection could possibly permit the evolution of apparently severe deleterious traits, such as sterility or inviability, proved much harder to explain. Darwin could find no satisfactory solution to this fundamental problem and, therefore, called it the *"mystery of mysteries"*.

This *"mystery of mysteries"* remains one of the important and unanswered questions in biological research: how do two species evolve from one? Speciation research became more tractable when Ernst Mayr helped define speciation as the evolution of reproductive isolation. Mayr's Biological Species Concept states that *"species are truly or potentially interbreeding natural populations that are reproductively isolated from other such groups"* (Mayr 1942). Thus, genetic studies of speciation could be recast into a more tractable problem: the genetic basis of reproductive isolation. Theodosius Dobzhansky made further progress in the study of speciation by classifying different reproductive isolating barriers into discrete, manageable categories (Dobzhansky 1937). Thus, "prezygotic" isolating barriers (e.g., behavioral isolation) act before a hybrid zygote is formed, whereas "postzygotic" isolating barriers (hybrid sterility or inviability) act after a hybrid zygote is formed.

As Darwin recognized, postzygotic isolating barriers are a seemingly counterintuitive phenomenon. Why would natural selection permit, let alone favor, the onset of genetic barriers that diminish the prospect of successful reproduction? A significant step towards the theoretical resolution of this paradox emerged in the early 1900's. Bateson, Dobzhansky and Muller independently suggested a genetic model of the evolution of postzygotic isolation that addressed this problem. In particular, they showed how hybrid sterility or inviability could evolve unopposed by natural selection. A simple two-locus version of the Dobzhansky-Muller model (Figure 1) considers a species that is split into two geographically isolated populations. Initially, both populations are genetically identical, having an *AA* genotype at one locus and *BB* at another. An allele *a*, compatible with both *A* and *B*, appears and is fixed in one population (*aaBB*). Similarly, an allele *b* appears and is fixed in the other population (*AAbb*). The key point of the model is that, while the newly emerged *a* and *b* alleles function properly in their respective genetic backgrounds, natural selection has not tested *a* and *b* together as they have never appeared together in the same genome. Thus, when hybrids between the two populations are formed, there is no guarantee that *a* and *b* will function properly in a common genome. The possible result of a negative epistatic interaction between *a* and *b*, referred to as a Dobzhansky-Muller incompatibility, is sterility or inviability of hybrids.

The Dobzhansky-Muller model enjoys considerable empirical support and is now well established as the appropriate theoretical framework for understanding the evolution of intrinsic postzygotic isolation (Coyne, Orr 2004). This has helped advance speciation research from classical genetic studies to identifying individual genes that cause hybrid incompatibilities. The identification of genes that cause hybrid sterility or inviability is an indispensable step towards a deeper understanding of speciation, and provides one of the most promising – but challenging – problems in evolutionary genetics. Several hybrid inviability genes have been identified so far, with most of the successes coming from crosses between the model genetic system *Drosophila melanogaster* and its sister species *D. simulans*. The melanogaster species subgroup consists of four species of *Drosophila* that are believed to have diverged approximately 2.5 million years ago (Figure 2). This group of species has attracted a lot of attention in the field of speciation because it includes *Drosophila melanogaster*, which is the model organism of choice for many genetic and genomic studies. Crosses between *D. melanogaster* and the other three species yield only inviable or sterile progeny in both sexes. These hybrid progeny can be inviable, depending on the direction of the cross (i.e., which species is maternal) and this has provided a basis to genetically dissect the causes of hybrid inviability. The isolation of naturally occurring strains that rescue hybrid inviability (Watanabe 1979; Hutter, Ashburner 1987; Sawamura, Taira, Watanabe 1993; Sawamura, Watanabe, Yamamoto 1993) and the availability of the formidable genetic toolkit in *D. melanogaster* has facilitated the rapid discovery of hybrid inviability genes (Presgraves 2010; Maheshwari, Barbash 2011).

Figure 1. The Dobzhansky-Muller model.

In contrast to hybrid inviability, which often arises later during the accumulation of reproductive isolating barriers, hybrid male sterility is one of the earliest evolving postzygotic barriers between geographically isolated populations. The identification of the hybrid male sterility genes in young species pairs is, therefore, essential for insights into the evolution of reproductive barriers relevant during the earliest stages of speciation. Unfortunately, far fewer hybrid sterility genes are known thus far than ones that cause hybrid inviability. One major reason for this discrepancy is that the powerful tools and rich history of mutations in *D. melanogaster* have not been as useful from the perspective of the study of hybrid sterility due to its older divergence from its sister species (with the exception of *JYalpha*, which is a case of gene transposition (Masly et al. 2006)). Evolutionary geneticists have, instead, focused on identifying hybrid sterility genes in crosses involving young, non-model species pairs.

Figure 2. The melanogaster species subgroup of *Drosophila*.

Recent work on hybrid sterility genes in two young *Drosophila* species pairs have begun providing a deeper understanding of the phenomenon of hybrid sterility at the molecular level and of the particular biological forces that drive the evolution of hybrid sterility genes. First, the case of *Odysseus*, which causes hybrid sterility between *Drosophila simulans* and *D. mauritiana*, has highlighted the role of rapidly evolving heterochromatin and heterochromatin-binding proteins in the evolution of hybrid male sterility. Second, the case of *Overdrive*, which causes hybrid male sterility between two subspecies *Drosophila pseudoobscura* USA and Bogota, has provided one of the first direct lines of evidence for the role of genetic conflict involving segregation distorters in the evolution of hybrid sterility. These insights from *Odysseus* and *Overdrive* have been largely complementary. *Odysseus* is one of the best-characterized hybrid sterility genes at the molecular level, with few hints about the biological processes that may have driven its evolution. *Overdrive* is one of the best-understood hybrid sterility genes with regards the evolutionary forces that drove the changes at this gene, but little is known about its action at the molecular level. Here, we review the genetic, evolutionary and molecular insights provided by these two hybrid sterility genes – *Odysseus* and *Overdrive* – and outline future research prospects.

ODYSSEUS

The melanogaster species subgroup consists of four species of *Drosophila* that are believed to have diverged approximately 2.5 million years ago (Figure 2). The study of hybrid sterility has focused on the three sibling species, *D. simulans* (a cosmopolitan species found worldwide), *D. mauritiana* and *D. sechellia* (both island species). These three species are believed to have diverged only about 250,000 years ago (Kliman et al. 2000). Every possible cross between these three species yields fertile females and sterile males. Because the females are fertile, they can be backcrossed to either parental species to yield introgression lines, in which genetic material from one species can be brought into a genomic background that is otherwise entirely from another species. This allows a genetic investigation of the factors that may cause hybrid male sterility. For instance, in 1993, this genetic introgression strategy

revealed the basis for a single chromosomal location, 16D, which when introduced from *D. mauritiana*'s X chromosome into the corresponding position of the *D. simulans* X chromosome caused complete male sterility (Perez et al. 1993). This genetic factor was named *Odysseus* ("who, in the well known epic, was the major figure hidden in the Trojan horse that in the end caused complete destruction of the foreign land it was brought into" (Perez et al. 1993)). Further genetic discussion suggested that a single gene of *D. mauritiana* origin at 16D along with a few other neighboring genes were required for the manifestation of complete male sterility (Figure 3).

Figure 3. Schematic of *D. mauritiana* introgressions into the *D. simulans* genomic background. The introgression that introduces the whole of *OdsH* from *D. mauritiana* is sterile.

Odysseus was the first animal hybrid sterility gene identified (Ting et al. 1998). It was found to encode a homeobox containing protein (hence the name *Odysseus site homeobox gene*, or simply *OdsH*). Homeoboxes are typically DNA-binding modules found in transcription factors and are highly conserved because of their important DNA-binding function. Intriguingly, the homeobox of *OdsH* had undergone rapid evolution, much more so than the rest of the protein-coding gene and even faster than neighboring intronic sequence. Further investigation revealed that the *OdsH* gene represented a gene-duplication from the *unc4* transcription factor, which is found in all metazoans (an evolutionary history spanning 700 million years) and is very slow to evolve. *OdsH* has evolved rapidly even in 250,000 years of *Drosophila* evolution, with 16 replacement changes having taken place in the 60 codon homeodomain, a remarkably high rate of evolution. Furthermore, whereas *unc-4* is expressed primarily in neural tissue, *OdsH* is exclusively expressed in testes, consistent with its role in potentially causing male hybrid sterility. Exactly what this role might be within species and how it might cause male hybrid sterility is still unknown.

The finding that *OdsH* is related to a known transcription factor (*unc-4*) and the finding that the DNA-binding determinant has evolved rapidly led to the proposal of a 'transcriptional incompatibility' model (Nei, Zhang 1998). Under this hypothesis, incompatibilities between the *OdsH* binding-specificity and sequence evolution of cis-acting sequence at the promoter/enhancer sequences of male meiotic (euchromatic) genes provide the underlying cause of hybrid sterility. This model is attractive because its been well documented that there

is significant transcriptional misregulation in hybrids, particularly in gonadal tissues (Meiklejohn et al. 2003; Michalak, Noor 2003; Michalak, Noor 2004). However, despite the initial attractiveness of a transcription-mediated sterility model, it raised several concerns.

Figure 4. Cytological localization of OdsH protein in *D. simulans* cell lines reveals a satellite DNA-binding function.

First, it was unclear why the protein: DNA interface of a gene important in male meiosis would tolerate rapid evolution. Indeed, one might expect such changes would be so detrimental that they would not have survived natural selection. More dramatically, it is even harder to favor gene regulation models that could account for the rapid evolution of this protein: DNA interface. Although there is now precedent for positive selection shaping at least some transcription factors and cis-regulatory elements (Landry et al. 2005; Haygood et al. 2007; Chen et al. 2012), progress at elucidating the molecular function of *OdsH* and the biological basis by which it causes male sterility was slow despite the identification of *OdsH* and the proposal of

the ‘transcriptional incompatibility’ model. This is especially surprising because for many years, *OdsH* was the only known hybrid sterility gene identified in *any* animal taxa.

An alternative ‘genetic conflict’ model posited that *OdsH* encodes a protein that binds to evolutionarily labile components of the genome, such as satellite DNAs found at centromeric or heterochromatic regions. In contrast to the ‘transcriptional incompatibility’ model, hypotheses of segregation distortion or centromere-drive can readily account for the rapid evolution of satellite-DNA sequences, and subsequently the rapid evolution of satellite-DNA binding proteins. Under this scenario, conflict between satellite DNA sequences and proteins that bind them provide the impetus for divergence of hybrid sterility genes. This scenario would predict that *OdsH* encodes a satellite-DNA binding protein. This model would further predict that *OdsH* evolution in *D. mauritiana* versus *D. simulans* should result in altered localization of OdsH binding in the *D. simulans* genome.

We previously tested the idea that *OdsH* encodes a satellite-DNA binding protein by expressing *OdsH^{sim}* fused to a FLAG epitope in a male *D. simulans* embryonic cell culture line (Bayes, Malik 2009). The punctate localization pattern of *OdsH^{sim}* was reminiscent of chromatin-binding proteins that localize to specific pericentric repetitive DNA sequences, in particular the AT-rich satellite binding protein D1. Antibody detection of the D1 protein, which is also known to localize exclusively to repetitive sequences on the *D. simulans* Y and 4th chromosomes (Figure 4A), provided a cytological ‘marker’ for comparing OdsH localization (Aulner et al. 2002). Indeed, immunostaining of D1 showed a distinct signal just adjacent to *OdsH^{sim}* localization (Figure 4B). In contrast, expression of an *OdsH^{mau}* fusion protein showed partial overlap with the D1 signal in *D. simulans* cells (Figure 4C). Co-expression *OdsH^{sim}* and *OdsH^{mau}* revealed that the two proteins share localization to a common site, but that *OdsH^{mau}* has an additional localization preference (Figure 4D). These experiments suggested that both *OdsH^{sim}* and *OdsH^{mau}* both encode satellite-binding proteins, which have altered localization specificities in the *D. simulans* genome.

Transgenic *D. simulans* fly lines that expressed N-terminal fusion proteins of 3xFLAG-*OdsH^{sim}* and Venus (Yellow Fluorescent Protein)-*OdsH^{mau}* allowed further study of the localization specificities of the *OdsH^{sim}* and *OdsH^{mau}* proteins in a system that allowed better chromosomal resolution. Visualization of localization patterns of the OdsH proteins in *D. simulans* larval neuroblast cells, whose chromosomes are often condensed by virtue of undergoing frequent cell division, provided an opportunity to map protein localization to individual chromosomes. These studies revealed that *OdsH^{sim}* localized to the X and 4th chromosome in larval neuroblasts, confirming the association of OdsH with repeat-rich regions of the *D. simulans* genome. In significant contrast, *OdsH^{mau}* shows gross localization to the *D. simulans* Y chromosome, which is also gene-poor and repeat-rich, while sharing localization with *OdsH^{sim}* to the pericentric region of the X chromosome and the 4th chromosome. Furthermore, the sites of OdsH localization displayed altered chromatin morphology and, in particular, the 4th and Y chromosomes show chromatin decondensation in both pure species and hybrid individuals.

To study the endogenously expressed *OdsH* function at a molecular level, we raised an antibody to the OdsH protein for cytological characterization of the OdsH protein in testes. Whole-mount immunochemistry of OdsH in *D. simulans* testes revealed that OdsH localization is punctate (2 dots representing the 4th and X chromosome) and is restricted to spermatocytes that have completed their 4 sequential mitotic divisions and are now increasing in cell volume as the chromosomes prepare for meiotic division. In the fertile introgression, OdsH staining is

also punctate within the pre-meiotic zone of the male testis (Figure 5A) similar to the wild-type, 'pure-species *D. simulans* case. In contrast, in the sterile introgression line, three dots including a new, intense staining on a third dot are observed (more easily visualized in Figure 5B, inset), which is presumed to be the *D. simulans* Y chromosome based on the earlier cytological characterization. Furthermore, the OdsH staining extends much beyond the testes in pure-species of fertile introgression *D. simulans* males. This indicates a dramatic expansion of the pre-meiotic zone in the sterile introgression testis, implying the activation of a meiotic checkpoint likely as a result of chromosomal abnormalities resulting from negative epistasis between *OdsH^{mau}* and the *D. simulans* genome.

Figure 5. OdsH antibody staining in whole mount testes of (A) fertile and (B) sterile introgressions.

Together, these studies clearly established that in contrast to the prevailing model, aberrant satellite-DNA binding underlies hybrid sterility. Moreover, the lack of endogenous *OdsH* expression in *D. mauritiana* testes further established that sterility does not result from the impairment of some necessary *OdsH* function, in transcription or otherwise. Instead, it clearly established a gain-of-function of *OdsH^{mau}* protein aberrantly binding and decondensing the *D. simulans* Y chromosome as the primary cause behind hybrid sterility. This study represented one of the first detailed characterizations of the molecular basis of hybrid male sterility caused by a genic incompatibility. It made clear that the emerging pattern of DNA-binding genes in hybrid incompatibilities may have little to do with transcriptional regulation and, instead, established the role of rapidly evolving heterochromatin and heterochromatin-binding proteins in the evolution of intrinsic reproductive isolation.

OVERDRIVE

Drosophila pseudoobscura pseudoobscura (hereafter referred to as the USA subspecies) is distributed across western North America, and is most famous as the subject of Dobzhansky's classic research on the fitness effects of chromosome rearrangements (Dobzhansky 1937). *Drosophila pseudoobscura bogotana* (hereafter referred to as Bogota) is found in regions of high elevation near Bogota, Colombia (Dobzhansky 1963) and is geographically separated from the USA subspecies by more than 2000km (Figure 6). The study of the genetic basis of hybrid male sterility in the Bogota-USA hybridization has a long history. The presence of *D. pseudoobscura* near Bogota, Colombia was known since DOBZHANSKY (1963), but these were thought to be a part of the main species range of *D. pseudoobscura*. However, hybrid male sterility between these taxa was documented almost a decade later (PRAKASH 1972). We now know that the USA and Bogota subspecies are young allopatric subspecies, estimated to have diverged between 150,000 and 230,000 years (Schaeffer, Miller 1991; Wang, Wakeley, Hey 1997). There is little prezygotic isolation between these subspecies (Noor 1995). The USA and Bogota subspecies are among the youngest studied hybridizations and provide a rare opportunity to understand the earliest steps in speciation.

Crosses between Bogota females and USA males produce F₁ hybrid males that are nearly completely sterile, whereas F₁ hybrid females and hybrids of both sexes from the reciprocal cross are completely fertile (Prakash 1972). Maternal effect was initially thought to play a large role in hybrid sterility (DOBZHANSKY 1974; ORR 1989a; ORR 1989b), but was later shown to be unimportant (Orr and Irving 2001). The large, essential role of the right arm of the Bogota X chromosome (XR) on hybrid sterility was first established through the use of the SR chromosome and the molecular marker *Esterase-5* (PRAKASH 1972). This result was largely forgotten until the *sepia* region on Bogota XR was shown to be essential for hybrid male sterility (ORR and IRVING 2001). Hybrid sterility appears to involve a single complex genetic incompatibility in which all loci are essential for the manifestation of full sterility. An interaction of Bogota alleles at loci on the right and left arms of the X chromosome (XR and XL, respectively) with dominant USA alleles on the second and third autosomes is necessary to cause hybrid sterility (Orr, Irving 2001). None of the important regions shows much effect individually on hybrid sterility because all interacting partners must be simultaneously present for the full expression of hybrid sterility. Because these genes are essential for sterility, they

represent the first Dobzhansky-Muller incompatibility to evolve between these populations. That is, these genes do not represent a mere additional layer of incompatibility on top of others; they are important *during* speciation.

Figure 6. Bogota and USA are young allopatric populations of *Drosophila pseudoobscura*.

This point is especially important because theory has shown that hybrid incompatibilities that underlie reproductive barriers should accumulate between taxa faster than linearly with divergence, a pattern known as the “snowball effect” (Orr 1995; Matute et al. 2010; Moyle, Nakazato 2010). This rapid accumulation of genic incompatibilities continues even after reproductive isolation is complete. Therefore, in older taxa, this process can confound the interpretation of the number of genes required to cause intrinsic reproductive isolation. Despite the identification of a few individual genes that are involved in hybrid incompatibilities, we do not know how many partner genes typically interact within a *single* incompatibility. Also, although a single hybrid incompatibility can, in principle, cause postzygotic isolation, it is difficult to estimate how many independent incompatibilities typically separate species. Finally, it is difficult to say which incompatibilities were important during speciation *versus* those that accumulated after the attainment of complete reproductive isolation. Mapping and identifying the interacting partner genes that form Dobzhansky-Muller incompatibilities in evolutionarily *young* hybridizations is, therefore, critical to understanding the genetic architecture of speciation.

Even though the sterility of hybrids between the *Drosophila pseudoobscura* Bogota and USA subspecies has been known for over 30 years, a study surprisingly found that the “sterile” F₁ hybrid males become very weakly fertile when aged and produce progeny that are almost all daughters (Figure 7) (Orr, Irving 2005). This sex-ratio distortion is not caused by hybrid inviability but by an overrepresentation of X-bearing sperm among the functional gametes: X-bearing sperm from F₁ hybrid males fertilize many more eggs than do Y-bearing sperm (Orr,

Irving 2005). The precise mechanism of segregation distortion is not well understood and may involve true meiotic drive (which acts during meiosis) or gamete killing (which acts after meiosis). In either case, the “cheating” *X* chromosome enjoys an evolutionary advantage. The genetic basis of segregation distortion in these hybrids is similar to that of hybrid sterility: Bogota alleles at loci on the right and left arms of the *X* chromosome (*XR* and *XL*, respectively) interact with dominant USA alleles on the second and third autosomes. Early genetic mapping had implicated the same region on Bogota *XR* in both hybrid phenomena (sterility and segregation distortion). The most important question was whether the two phenomena of segregation distortion and hybrid male sterility were related to each other. If so, this would provide evidence consistent with the long hypothesized role of genetic conflict involving segregation distorters in the evolution of hybrid sterility (Frank 1991; Hurst, Pomiankowski 1991). *Drosophila pseudoobscura* USA and Bogota provide a powerful system for answering not only questions about the genetic architecture of hybrid incompatibilities, but also the biological forces that drive the evolution of hybrid incompatibility genes.

Figure 7. “Sterile” hybrid males become weakly fertile when aged and produce mostly daughters.

To explore the relationship between segregation distortion and hybrid sterility, we fine mapped the genes responsible for sterility and segregation distortion within the *sepia* (*se*) region on *XR* (Phadnis, Orr 2009). 175 independent introgression lines were generated in which the USA *sepia* region was moved into an otherwise pure Bogota background. The resulting introgression lines, backcrossed for 28 generations, have genomes that derive almost entirely from Bogota except for a small chromosomal region near *sepia*. When females from these introgression lines are crossed to USA males, the resulting hybrid males are genetically

identical to F₁ hybrid males except for the small chromosomal region introgressed from USA. All 175 lines yielded hybrid males that were both fertile and produced normal (~50:50) sex ratios by virtue of now possessing USA alleles instead of the sterility-associated Bogota alleles. This defined a region that harbors the hybrid sterility and hybrid segregation distortion gene(s) (Figure 8).

Figure 8. Introgression mapping identifies the genetic region responsible for both hybrid sterility and segregation distortion.

To further refine the genetic mapping, Bogota females heterozygous for an introgression were crossed to USA males and *se*⁺ males were tested for ability to produce progeny. One such fertile *se*⁺ male was found; this male also produced progeny in an even sex ratio ('rescuing' the hybrid sterility phenotype). Genotyping this line localized the gene(s) causing hybrid sterility and hybrid segregation distortion to a 20kb region that includes only five predicted loci (Figure 8). This entire 20kb region from the Bogota subspecies was sequenced and compared to the homologous USA sequence from the *D. pseudoobscura* (USA) genome (Richards et al. 2005). Three of the five predicted genes—*GA23450*, *GA19787* and *GA19828*—showed no non-synonymous differences, while *GA23843* showed three non-synonymous differences. The predicted gene *GA19777*, however, showed eight non-synonymous changes, a surprising number given its small coding region (591 bp, excluding one 74 bp intron). Given that genes causing reproductive isolation often evolve rapidly (Presgraves 2010), *GA19777* (later named *Overdrive*), which features a DNA-binding motif, represented the best candidate for the cause of hybrid sterility and/or hybrid segregation distortion.

Figure 9. The USA allele of *Overdrive* (*GA19777*) rescues hybrid fertility.

To confirm whether *Overdrive* (*Ovd*) caused these hybrid phenotypes, transgenic experiments were performed to attempt to rescue the fertility of F_1 hybrid males with a transgenic copy of the (fertile) USA allele of *Ovd* (hereafter *Ovd*^{USA}). Males that inherit both transgenic *Ovd*^{USA} and endogenous *Ovd*^{Bog} are far more fertile and produce progeny significantly more often than those that inherit only the endogenous *Ovd*^{Bog} (Figure 9). Surprisingly, *Ovd*^{USA} transgenic hybrids, which rescue fertility weakly, still produce almost all daughters. Thus, while *Ovd*^{USA} transgenes rescue the hybrid sterility effect, they do not suppress segregation distortion. However, in the opposite direction, transgenes of *Ovd*^{Bog} resulted a strikingly female-biased sex ratio in the appropriate genetic background, whereas control males that inherit only the endogenous *Ovd*^{USA} produce normal sex ratios, clearly implicating the *Ovd*^{Bog} allele as playing a role in hybrid segregation distortion (Figure 10). Thus, the same allele of *Ovd*^{Bog} causes both hybrid sterility and segregation distortion. *GA19777* was named *Overdrive* (*Ovd*) because of its role in both segregation distortion (“meiotic drive”) and hybrid sterility. Interestingly, the effects of *Ovd* transgenes on hybrid sterility and segregation distortion are observed even in *trans*. For example, *Ovd*^{Bog} transgenes inserted on the autosomes can cause segregation distortion of the X chromosome in hybrids.

Ovd is predicted to encode a polypeptide with a single MADF DNA-binding domain near its C-terminus. As expected given its phenotype, RT-PCR revealed that *Ovd* is expressed in the testes of both pure subspecies males and in sterile F_1 hybrid males. Evolutionary analyses showed that all seven non-synonymous changes and all five synonymous changes fixed between Bogota and USA *Ovd* alleles occurred in the Bogota lineage — the lineage whose X chromosome causes hybrid sterility and hybrid segregation distortion. This significant enrichment of substitutions indicates accelerated evolutionary changes in the Bogota lineage, consistent with a history of segregation distortion at the *Ovd* locus in Bogota. The most profound aspect of the *Ovd* study was the demonstration that the same gene, *Ovd*, causes both

F₁ segregation distortion and hybrid sterility in evolutionarily young taxa that obey Haldane’s rule. This study provided the first direct evidence that genetic conflict is an important force in the evolution of postzygotic isolation.

Figure 10. The Bogota allele of *Overdrive* (*GA19777*) causes segregation distortion.

Figure 11. The genetic architecture of hybrid sterility and segregation distortion in Bogota-USA hybrids.

While *Ovd* is necessary to cause hybrid male sterility or segregation distortion, it is not sufficient by itself to cause either phenomenon. That is, it requires “correct” alleles at several interacting loci to yield complete hybrid sterility or segregation distortion. How many such interacting loci are involved in the hybrid incompatibility responsible for male sterility? This

question remained unanswered even in the context of loci on the Bogota *X* – the best characterized chromosome in this hybridization. Questions also remained about the genetic architecture of segregation distortion in hybrid males and its suppression in pure Bogota males. More important, are all loci involved in hybrid sterility also involved in segregation distortion, as in the case of *Ovd*?

To address these questions, we performed genome-wide mapping of all loci involved in hybrid male sterility and segregation distortion (Phadnis 2011). Separate crosses were performed to map the factors on the *X* chromosome and the autosomes. The crosses for mapping the factors on the *X* chromosome controlled for the effects of *Ovd* to maximize mapping power for the loci that interact with *Ovd*. The crosses for mapping the factors the autosomes used a *sepia* introgression line analogous to a ‘fertility rescue mutation’ to maximize mapping power for dominantly acting loci that interact with *Ovd*. These analyses reveal a coherent picture that implicates an interaction of *Ovd* with only two major effect loci (one on Bogota *XL* and another on the second chromosome) and with a few minor modifier loci) in a single dominant hybrid incompatibility as the genetic basis of hybrid sterility (Figure 11). This is one of the most comprehensively described genetic network of Dobzhansky-Muller incompatibilities in speciation, and lays the foundation for fine mapping experiments to identify *all* the genes that interact with *Ovd* to cause sterility in hybrid F1 males between the Bogota and USA subspecies of *D. pseudoobscura*. Since postzygotic isolation between Bogota and USA involves a single incompatibility with a modest number of interacting loci, identification and characterization of these genes will provide important insights into the molecular nature of postzygotic isolation between species.

The genetic architecture of segregation distortion and its suppression is even simpler: *Ovd* interacts with only two loci on the Bogota *X*-chromosome to cause segregation distortion, which is nearly completely suppressed by a single locus on the Bogota second chromosome. Most important, the loci that cause hybrid males sterility and segregation distortion are partially – but not completely – overlapping. Of particular interest is the *X22* locus, which appears to be required for hybrid male sterility but not for segregation distortion. If the effects of *X22* on segregation distortion and hybrid sterility prove to be separable, then the *X22* locus can be represented as the genetic switch that converts a segregation distortion system *within* species into a hybrid sterility system *between* species. Identifying the gene that underlies this tipping point from segregation distortion to hybrid sterility holds the promise of providing insight into the events that lead to reproductive isolation between incipient species and explaining with greater clarity how segregation distortion can set the stage for speciation.

CONCLUSION

The studies of *Odysseus* and *Overdrive* provide largely complementary insights into the molecular and evolutionary basis of hybrid sterility. The cell biological study of *Odysseus* – the first hybrid sterility gene to be discovered – has provided one of the first hints into the molecular nature of hybrid sterility and into the mechanisms of hybrid dysfunction. In particular, localization studies of alternative alleles of *OdsH* in cell culture and in flies have revealed how evolutionary gains of function in the context of DNA-binding specificities can drive functional divergence of genes that cause hybrid incompatibility. Further, the chromatin

decondensation defects caused by *OdsH* provide a molecular view into the mechanisms of hybrid dysfunction and highlight the role of the dynamic evolution of heterochromatin in intrinsic postzygotic isolation.

While *Odysseus* has provided a strong study case for the functional and molecular aspects of hybrid sterility, questions about the genetic architecture of the hybrid incompatibility that *OdsH* participates in and the biological forces that drove its rapid evolution remain open. First, it is unclear how many genes *OdsH* interacts with to cause hybrid sterility. *OdsH* alone is insufficient to cause complete hybrid sterility and needs to interact with other *X*-linked genes included in the introgression from *D. mauritiana*. The sterile introgression that harbors *OdsH* is present in an otherwise *D. simulans* background. Therefore, there may be additional *D. simulans* components that may also be involved in this incompatibility. This also makes it difficult to say whether the *OdsH* incompatibility is recessive (contributes to the sterility of F2-like hybrids) or dominant (contributes to F1 hybrid male sterility). Second, the findings of *OdsH* chromosomal localization, the apparent antagonism of heterochromatin by chromatin decondensation, and protein expression patterns in the testes lead to possible genetic conflict scenarios in causing male hybrid sterility. One scenario posits that the *X*-linked *OdsH* protein may participate in segregation distortion in males, recognizing a *Y*-satellite to cause decondensation and, thereby, the failure of *Y*-bearing sperm. Due to the deleterious effects of this *X*-drive (reduced fertility, skewed sex ratios), autosomal and *Y*-linked suppressors would arise in each population. However, introgression of *OdsH^{mau}* into the *D. simulans* genome (as seen in hybrids) may unleash hidden distortion that had been successfully suppressed in *D. simulans* (Frank 1990; Hurst, Pomiankowski 1991). While few clues currently explain the exact biological processes that drove the rapid evolution between *D. mauritiana* and *D. simulans*, further characterization of the sites of localization of *OdsH* and the meiotic defects in the sterile hybrid testes may help differentiate alternative models.

In contrast to *Odysseus*, the biological force that drove the evolution of *Overdrive* is more obvious. The idea that genetic conflict between segregation distorters and its suppressors may drive the evolution of hybrid sterility between populations is very intuitive, but the lack of empirical evidence hindered its mainstream acceptance. The demonstration that *Ovd* causes both segregation distortion and hybrid male sterility in the *D. pseudoobscura* USA-Bogota hybrids finally connected the two phenomena in the context of speciation. The simplest versions of the theory that segregation distortion can drive the sterility of inter-species hybrids often invoked at least two independent segregation distortion systems in two populations. For example, *X*-chromosome distortion suppressed in Bogota and *Y*-chromosome distorters suppressed in USA can both get de-repressed in their F1 hybrids. The Bogota *X*-chromosome distorter may kill all *Y*-bearing sperm and the USA *Y*-chromosome distorter may kill all *X*-bearing sperm, thus rendering the hybrid sterile. We can now reject this simplest version of the theory in the case of the USA-Bogota hybrids: while the Bogota *X*-chromosome participates in segregation distortion, there is no evidence of segregation distortion carried out by the USA *Y*-chromosome. How might a single segregation distortion system cause the complete sterility of hybrids? One plausible explanation is that, in hybrids, the strength of the *X*-chromosome distortion may be beyond levels ever experienced during the repeated bouts of the arms race between segregation distorter and suppressor alleles in the evolutionary history of the Bogota lineage. This may result in the killing of not only the sensitive *Y*-bearing sperm, but also the normally more resistant *X*-bearing sperm, leading to the near complete sterility of the hybrid males.

A comprehensive picture of the genetic architecture of hybrid sterility and segregation distortion may help address the above question from a molecular viewpoint. Our genome-wide analyses revealed that the single hybrid incompatibility that isolates USA and Bogota consists of only a small number of interacting components, making it possible to identify the complete complement of genes essential for reproductive isolation (Phadnis 2011). The loci essential for hybrid sterility nearly overlap with those that are involved in segregation distortion and its suppression. Identifying the apparent exception to this overlap – the X22 locus on the Bogota X-chromosome, which appears to be essential for hybrid sterility but not for segregation distortion – may hold the key to addressing how a single segregation distortion system within a population may cause complete sterility in hybrids.

While the role of *Odysseus* in binding heterochromatin is now demonstrated clearly, the molecular function of *Overdrive* and the mechanism by which it causes segregation distortion remains an open line of inquiry. Because *Ovd* is involved in specifically killing Y-bearing sperm, it appears likely that it may function through binding to heterochromatin, perhaps Y-specific heterochromatin, in a mechanism that is analogous to that of *Odysseus*. Ongoing functional studies to characterize the function of *Ovd* within species and its mechanism of hybrid sterility between species may reveal whether *Odysseus* and *Overdrive* are fundamentally similar in their causes of evolution and their mechanisms of causing reproductive isolation.

Given the relative paucity of genes directly implicated in hybrid sterility in animals, the molecular insights obtained from *Odysseus* and the evolutionary genetic insights obtained from *Overdrive* will not only help elucidate each other's underlying biology but may also reveal potentially common themes associated with hybrid sterility in other systems.

Chapter 10

THE ROLE OF TRANSPOSABLE ELEMENTS IN SPECIATION

Eric T. Watson and Jeffery P. Demuth*

Department of Biology, The University of Texas at Arlington, Arlington, TX, US

ABSTRACT

With innovative DNA sequencing technologies has come a new appreciation for the content of animal and plant genomes. Overwhelmingly, a picture has been painted in which mobile and repetitive elements dominate the genomic landscape. Mobile genetic elements have recently been shown to contribute coding and regulatory sequences during their proliferation, leading to functional and regulatory novelty as well as element-mediated rearrangements coinciding with speciation events. Additionally, dormant elements occasionally erupt in bouts of excision and transposition in interspecific hybrids, resulting in a suite of maladaptive traits. The potential for mobile elements as key players in the evolution and diversification of genomes and species is immense yet in many respects transposable elements still remain the “dark matter” of the genome. This is particularly true of their role in speciation, and in order to fully appreciate their role, much work is still needed. In this chapter, we investigate the evidence for transposable elements as drivers of diversification and speciation.

INTRODUCTION

Transposable elements (TEs) are a diverse group of genetic sequences that share the common ability to move within a genome. The broadest distinction among TEs classifies them based on whether or not transposition involves an RNA intermediate (Wicker et al., 2007). Retrotransposons (class I TEs) transpose through a replicative “copy and paste” mechanism, which involves the production of a processed mRNA transcript that becomes re-inserted into the host genome after being reverse transcribed into complementary DNA by an element-

encoded reverse transcriptase. In contrast, DNA transposons (class II TEs) rely on a non-replicative “cut and paste” mechanism, involving a diversity of element-encoded enzymes, such as transposase, C-integrase, and tyrosine recombinase. Both class I and class II TEs are prone to proliferative bursts and exist as either autonomous elements, which encode the proteins necessary to catalyze their own transposition; or non-autonomous elements, which use the replication machinery of autonomous TEs.

TEs are often considered “parasitic” and “selfish” due to their ability to invade a genome despite imposing a fitness cost to their hosts in the process. By inserting themselves into coding or regulatory regions, TEs often have deleterious consequences, but their impact varies among taxa. For instance, TE mobilization is associated with over 100 human diseases (Goodier and Kazazian 2008; Belancio, Hedges, and Deininger) but this represents a relatively low percentage of pathogenic mutations (~0.3%; (Callinan and Batzer 2006; Kazazian 1998). Whereas, in mouse and *Drosophila*, TE insertions constitute a much larger proportion of deleterious mutations (10% and 50% respectively; Maksakova et al. 2006; Finnegan 1992). The variation in how deleterious TEs are likely reflects an interaction between host genome defense and variation in the composition of TE types (Eickbush and Furano 2002).

While TEs are perhaps best known for their capacity to disrupt host gene function, speculation about their potential evolutionary benefits as drivers of diversity have been around almost since their discovery in the 1940s (McClintock 1950; 1956; Britten and Davidson 1971). However, it was not until the genomic era that the ubiquity, abundance and diversity of TEs has been fully appreciated (Kidwell and Lisch 2001; Fedoroff 2012). For example, variation in TE abundance between the genomes of different species reveals lineage specific dynamics in the composition and abundance of different classes of TEs. Recent large-scale sequencing projects and advances in the screening of genomic sequences for hallmarks of repetitive elements reveal that TEs comprise 10-90% of plant nuclear genomes (Li et al. 2004; Haas et al. 2005), up to 20% of fungal genomes (Wicker et al. 2007), 9% of the chicken genome (International Chicken Genome Sequencing Consortium 2004), 15-22% of the *Drosophila melanogaster* genome (Kapitonov and Jurka 2003; Biemont and Vieira 2005), 6-17% of the *Tribolium castaneum* genome (Wang et al. 2008), and 50-66% of the human genome (International Human Genome Sequencing Consortium 2001; Koning et al. 2011). However, given that identifying TEs and their copy number from genomic sequence is fraught with computational difficulties, some of these values likely remain underestimates (e.g., Koning et al. 2011). Across eukaryotes, TEs are a much better predictor of genome size than protein coding gene content (Feschotte and Pritham 2007a). In addition to their abundance, a handful of well-annotated genomes illustrate that the TEs present in eukaryotes are very diverse (Wicker et al. 2007; Mandal and Kazazian 2008; Venner et al. 2009; Jurka et al. 2011; Chénais et al. 2012).

The diversity of genetic novelty infused by TE invasion and proliferation has been a fundamental argument for their role in driving organismal diversity (reviewed in Fedoroff 1999; Kazazian 2004; Biémont and Vieira 2006; Oliver and Greene 2009; 2011) and there are a growing number of specific examples where TE domestication has contributed coding and/or regulatory sequences implicated in adaptive novelty (Brandt et al. 2005; Feschotte and Pritham 2007b; Feschotte 2008; Butter et al. 2010). Furthermore, the burst dynamics of TEs wherein they invade, rapidly proliferate, and then are silenced by host defense has been hypothesized to explain broad evolutionary patterns from geological time scales to contemporary biodiversity (Zeh et al. 2009; Oliver and Greene 2011; Table 1).

Table 1. Mobile genetic elements and speciation in geologic time

TE event/Species history	Reference
Reduced L1 and SINE accumulation during radiation of African apes (14–15 Mya).	Intl Hum Gen Seq Consort (2002)
Expansion of L1 subfamilies parallels intense speciation in <i>Rattus sensu stricto</i> .	Verneau <i>et al.</i> (1998)
Lx family amplification is concomitant to the radiation of murine mammals.	Pascale <i>et al.</i> (1990)
Rapid speciation in the genus <i>Taterillus</i> (gerbil) occurred along with intense activity of TEs in nascent lineages.	Dobigny <i>et al.</i> (2004)
Intense DNA elements transposition during the <i>Myotis</i> radiation.	Ray <i>et al.</i> (2008)
DNA transposon bursts parallel speciation events in pseudo tetraploid salmonids and occurred after genome duplication.	de Boer <i>et al.</i> (2007)
Acquisition and consequent transposition of an endogenous retrovirus (ERV) element and lineage specific enrichment of TEs in <i>Entamoeba histolytica</i> .	Lorenzi <i>et al.</i> (2008)
Repeated bouts of Haplochromine-specific SINE insertions followed by extensive radiations found in all inhabited lakes.	Shedlock <i>et al.</i> (2004)
Peak L2 and MIR activity coincides with marsupial-placental split 120-150 MYA.	Kim <i>et al.</i> 2004
Peak L1 activity corresponds to the eutherian radiation 100MYA.	Kim <i>et al.</i> 2004
Unprecedented LTR activity on the Y-chromosome corresponds to the K-T ecological disturbance 70 MYA	Kim <i>et al.</i> 2004
Alu and young L1 activity is restricted to the radiation of Old World and New World monkeys 40 and 25 MYA, respectively.	Kim <i>et al.</i> 2004
Diverse species exhibit different numbers of TE families between subpopulations with relatively low amounts of sequence divergence (0-561 families at < 1% and 5-1093 families at < 5% divergence)	Jurka <i>et al.</i> 2011
Tourist-like MITE, miniature Ping (mPing), present in 14 copies in <i>Oryza indica</i> and 70 copies in <i>O. japonica</i> .	Jiang <i>et al.</i> 2003
<i>Ty3/gypsy</i> -like retrotransposon expansion in hybrid species <i>H. anomalus</i> , <i>H. deserticola</i> , and <i>H. paradoxus</i> occurred near the time of their origin 0.5 to 1 Mya.	Ungerer <i>et al.</i> 2009

Transposable element activity in the following examples is concordant with phylogenetic activity of their hosts. Additional examples describe intraspecific diversity in numbers of TE families.

Despite evidence suggesting a role for TEs as drivers of organismal diversity, it does not necessarily follow that TEs are important to the process of speciation. In sexually reproducing species, speciation is the process of converting segregating variation within a species to fixed differences between species through the evolution of reproductive isolation (Dobzhansky 1937; Mayr 1942). Darwin's theory of natural selection, while providing an elegant mechanism for adaptation, did not fully explain how speciation *per se* occurs. The logical difficulty that arises is that selection should weed out variants causing reduced fitness in conspecific matings (Orr

1996). For this reason, even if we assume that TEs are broadly important to biodiversity, it is also worthwhile to address whether they might play a special role in generating isolation.

Thirty years ago Rose and Doolittle (1983) authored a paper in *Science* titled “Molecular Biological Mechanisms of Speciation” in which they examined the empirical evidence for repetitive DNA’s role in the formation of reproductive isolation. It marked an early synthetic effort to relate TEs to the process of speciation. In their review, the mechanisms by which TEs might facilitate the origin of species were subdivided into three general categories: I) Genomic Disease, II) Mechanical Genome Incompatibility, and III) Genome Resetting. Based primarily on what was then recent data demonstrating hybrid dysgenesis between P and M strains of *Drosophila melanogaster*, Rose and Doolittle concluded that Genomic Disease, while seemingly least plausible, had more empirical support than the other two categories. We have learned much in the intervening three decades and in this chapter we will revisit the categories of Rose and Doolittle as a convenient conceptual scaffold for understanding the variety of ways TEs might directly, or indirectly, cause reproductive incompatibility.

MECHANISM I: GENOMIC DISEASE

The view that TEs are genomic parasites lends itself naturally to the hypothesis that antagonistic coevolution between disease (the TEs) and immunity (the host’s genomic defenses) might promote speciation. Much like how B and T cells of the vertebrate adaptive immune system recognize and remember specific pathogens, a host’s need to suppress the deleterious effects of selfishly proliferating TEs may drive specificity of host genomic defenses against their particular complement of TEs (Ironically, TE domestication contributes to the V (D)J recombination system that makes adaptive immunity to pathogens possible; Market and Papavasiliou 2003; Zhou et al. 2004; Kapitonov and Jurka 2005; re- viewed in Litman et al. 2010). Consequently, populations evolving in allopatry that are exposed to different TE pressures may diverge in genomic defense as well.

There are a few ways this genomic disease model could result in reduced fitness for F_1 hybrids. First, since F_1 s are haploid for both parental genomes, to the extent that defense mechanisms are haploinsufficient, TEs from both parental types may escape suppression. Second, if the contribution to defense is inherited primarily from one parent but not the other, TEs from the non-contributing parent might be freed from suppression. Uniparental inheritance of defense is particularly intriguing because it predicts asymmetries in hybrid breakdown. For instance, it is straightforward to imagine that uniparental defense could result in “Darwin’s corollary”, which observes that hybridization barriers are often asymmetric (i.e., the degree of isolation depends on which population is the maternal vs paternal parent; see Turelli and Moyle 2007). If a population that has adapted to invasion by a novel TE hybridizes with a naïve population, hybrids in only one direction will suffer. Additionally, since sex-limited chromosomes (Y or W) tend to accumulate TEs disproportionately relative to the rest of the genome (Charlesworth et al. 1994; Abe et al. 2000; Bachtrog 2005; Charlesworth et al. 2005) the heterogametic sex may be more likely to suffer in the F_1 . For example, if XX mothers contribute to defense, XY hybrid sons might be affected disproportionately because they will not be guarded against TEs originating from their father’s Y chromosome. The expected pattern

of heterogametic F_1 hybrids suffering disproportionately is consistent with a “rule of speciation”, Haldane’s rule (Haldane 1922).

Figure 2. Sense and anti-sense orientation of matching TEs are indicated by black and red arrows. Sense (A locus) and antisense (B locus) transcription are indicated by squiggle lines. Here the B locus produces antisense transcripts which initiate small RNA production and target silencing of the A locus. For simplicity only the haploid genome is illustrated except in hybrids.

If we further abstract the genomic disease model to a two locus genetic interaction model wherein A_1 and A_2 represent TE variants, and B_1 and B_2 represent matching variants at a host defense locus, the history of work surrounding the Dobzhansky-Muller (DM) model of post-zygotic isolation become immediately relevant (Figure 1). While a complete reconciliation of the genomic disease model with DM is outside our scope, it is a potentially interesting avenue for future work. The mathematical framework surrounding DM is well developed (e.g., Turelli and Orr 2000; Orr and Turelli 2001; Demuth and Wade 2005) as is the population genetic

theory for TE proliferation (Charlesworth and Charlesworth 1983; Charlesworth and Langley 1989; Ribeiro and Kidwell 1994; Brookfield and Badge 1997). Reconciling the two may facilitate more specific predictions about the strength of asymmetry and consequences of lineage specific divergence.

TE Suppression by Small RNAs: A Molecular Mechanism for Speciation

While it is not the only mechanism by which TE activity can be controlled, the small RNA “immune response” to TEs represents an ancient, pan-eukaryotic, genomic defense against TE mobilization, and provides the kind of host-pathogen specificity necessary for antagonistic coevolution (reviewed in Aravin et al. 2007; Girard and Hannon 2008; Malone and Hannon 2009; Michalak 2009; Bourc’his and Voinnet 2010; Castillo and Moyle 2012). Small RNA-mediated TE control happens in three basic phases: detection, amplification, and repression (Girard and Hannon 2008). First, the detection phase relies on TE’s propensity to produce anti-sense, double-stranded, or aberrant RNAs, which are recognized by core RNAi machinery (e.g., Dicer RNase III family proteins) and are cleaved into small RNAs such as endogenous siRNAs. During the amplification phase, the primary pool of siRNAs are copied by an RNA dependent RNA polymerase and associate with Argonaute proteins (Ghildiyal et al. 2008). These siRNA - Argonaute complexes then recognize complimentary RNA sequences, guiding cleavage of additional transcripts. Depending on the taxon and tissue, TE repression is ultimately achieved by a combination of transcript degradation (post-transcriptional silencing) and/or siRNA target directed methylation and/or histone modification (transcriptional silencing).

In animals, there is an additional detection mechanism that provides protection to the germline and takes advantage of TE’s unique ability to move within the genome, the piwiRNA pathway. Rather than relying on Dicer dependent dsRNA recognition as above, detection begins with antisense transcription of TEs that have transposed into special RNA gene clusters (e.g., the flamenco locus in *Drosophila* contains sequences that repress Gypsy, Idefix and ZAM family TEs; Pelisson et al. 1994; Prud’homme et al. 1995; Sarot et al. 2004). Processed transcripts from these clusters, called piRNAs, associate with members of the Piwi subfamily of Argonaute proteins (e.g., *Drosophila*: Piwi, Aubergine, AGO3; Mouse: Miwi, Mili, Miwi2). Amplification occurs by a “ping pong” cycle wherein the antisense piRNAs direct cleavage of sense strand TE RNAs which also associate with Piwi proteins that then target cleavage of additional antisense piRNAs...and so on. Post-transcriptional and transcriptional repression is ultimately achieved similarly to that of the siRNA pathway above.

While we have provided only the coarsest overview, it should be clear that the genomic disease - immune response analogy is an apt one despite predating discovery of small RNA mediated TE control by more than a decade (Bingham et al. 1982; Rose and Doolittle 1983; Ginzburg et al. 1984). Breakdown at any of the three stages of small RNA mediated TE control could result in hybrid problems. At detection, uniparental inheritance of small RNA is predicted to be particularly problematic, and haploinsufficiency could follow from problems in the amplification phase. Inadequacy of either of these phases would be expected to result in breakdown of repression.

EVIDENCE FOR MECHANISM I

Drosophila Hybrid Dysgenesis

Early evidence (in fact motivation) for the genomic disease model came from two independent systems in *Drosophila* (P-M and I-R) where crossing different strains of *D. melanogaster* resulted in hybrids with a suite of maladaptive traits such as sterility, gonad hypertrophy, extensive chromosomal aberrations, male recombination, and elevated germline mutation (Picard and L'Héritier 1971; Kidwell and Kidwell 1975; Picard 1976; Engels and Preston 1979; Schaefer et al. 1979; Hiraizumi et al. 1973; Yamaguchi, 1976; Kidwell et al. 1977; Woodruff and Thompson, 1977; Thompson et al. 1978) These studies also revealed that age and rearing temperature impact the degree of hybrid phenotypes (Picard 1976; Bucheton et al. 1976) and collectively the consequences of these crosses was termed “hybrid dysgenesis” (Kidwell et al. 1977).

The underlying cause of hybrid dysgenesis was eventually traced to TE activity in offspring of P x M crosses and I x R crosses (Pelisson 1981; Rubin et al. 1982; Bingham et al. 1982; Kidwell 1983; Bucheton et al. 1984). In both cases strains more recently collected from the wild had active TEs that were not present in long-time lab strains. Hybrid dysgenesis only occurred in these crosses when the paternal parent carried the autonomous TE and the maternal parent did not. In the I-R system dysgenesis only arises when inducer (I) strain males are crossed to reactive (R) strain females. In the P-M system dysgenesis only occurs when paternal (P) strain males are crossed with maternal (M) strain females (Kidwell et al. 1977; Bingham et al. 1982; Kidwell 1983). The asymmetry in consequences of these crosses, particularly I-R sterile hybrid females, suggested that a maternal factor is responsible for offspring's ability to control inherited TEs (Bregliano et al. 1980).

Discovery that members of the Piwi subfamily of Argonaute proteins are maternally loaded into the pole plasm that will give rise to the future germline, and are necessary for TE silencing (Reiss et al. 2004; Sarot et al. 2004), added to early evidence for maternal inheritance of TE repression (Jensen et al. 1999). Later, small RNAs were also shown to be inherited maternally (Blumenstiel and Hartl 2005) and the protein-RNA complexes are responsible for TE silencing through females. Since the cytoplasm is mostly discarded from sperm there is little opportunity for male transmission of small RNAs. Thus, the hybrid dysgenesis observed in P-M and I-R hybrids appears to result from uniparental (maternal) inheritance of piRNA based TE control and the consequent inability to silence paternally derived TEs (Brennecke et al. 2008). Furthermore, maternal piRNA mediated suppression of TEs in the germline appears to be widely conserved among animals (reviewed in O'Donnell and Boeke 2007).

TE Derepression in Interspecific Animal Hybrids

Even before the mechanisms of small RNA based TE silencing were well worked out, researchers sought to test predictions of TE-mediated speciation in a comparative framework by looking for similar phenotypes in additional *Drosophila* hybrids (Coyne 1986; Hey 1988; Coyne 1989). These experiments assayed hybrids from isofemale lines derived from natural populations, as well as hybrids between natural and laboratory mutant lines. Enthusiasm over

the role of TEs in speciation subsided, when it appeared that hybrid dysgenesis was not a ubiquitous feature of interspecific hybrids from the *D. melanogaster* or *D. affinis* subgroups (Coyne 1985; 1986; 1989; Eanes et al. 1988).

Additionally, even in *Drosophila* systems where hybrid dysgenesis occurs, sterility often varies with temperature and age. This provides an opportunity for previously naïve populations to adapt to new elements; perhaps mirroring the invasion of novel TEs within populations. For example, by repeatedly crossing males from an I strain to older dysgenic females that had regained some fertility, Péliçon and Bregliano (1987) were able to introduce repression of I element proliferation in a previously reactive genome within 15 generations. Based primarily on the *Drosophila* findings, Coyne (1986) suggested that to demonstrate a convincing case for TEs causing speciation requires:

- (1) a difference in the distribution of element families among species,
- (2) that these differences cause reproductive isolation (temperature-sensitive gonadal dysgenesis or elevated mutation and recombination rates do not themselves result in isolation)
- (3) the existence of reciprocal sterility effects of the elements in cases where sterility occurs in reciprocal crosses between species.

Despite early pessimism, new findings from *D. melanogaster* x *D. simulans* hybrids have helped fuel renewed interest in TEs role in speciation. For example, Kelleher et al. (2012) recently showed that in contrast to intraspecific *D. melanogaster* crosses where maternal transmission of piRNAs fails to silence active paternal TEs, the interspecific hybrids have widespread activation of both maternally and paternally derived TEs. The study also showed that hybrid offspring are phenotypically most similar to flies with mutations in piRNA pathway genes (e.g., *Piwi*, *Aubergine* and *Argonaut3*). Ten proteins in the piRNA pathway showed excess amino acid changes between *D. melanogaster* and *D. simulans* suggesting a model wherein divergence in piRNA effector proteins between species is responsible for TE derepression in hybrids (Kelleher et al. 2012).

Several other studies also now provide evidence for both lineage-specific evolution of TE families (Table 1) and elevated activity of TEs in interspecific animal hybrids. For example, hybrids between *Drosophila koepferae* and *D. buzzati* experience increased *Osvaldo* transposition, a TE present in a repressed state in both parent genomes (Labrador et al. 1999). In mammals, hybrids between the kangaroo species *Macropus rufogriseus* and *M. agilis* exhibit unstable centromeres due to the expansion of KERV-1 TEs (Metcalf et al. 2007). Hybrids between the Wallaby species *M. eugenii* and *Wallabia bicolor* also experience elevated TE activity, leading to the expansion of centromeric heterochromatin (O'Neill et al. 1998). In lake whitefish (*Coregonus spp.*), evidence for an increase in TE activity was revealed by sequencing the transcriptomes of hybrids between normal and dwarf species (Renaut et al. 2010).

TE Derepression in Plant Hybrids

There are also several examples of TE proliferation in hybrid plants that are consistent with the genomic disease model. Indeed, McClintock's original observations of mosaic maize kernels that lead to the discovery of TEs and motivated her genomic shock hypothesis (McClintock

1950; 1984), are broadly compatible with the genomic disease model. Furthermore, the first mechanistic example of genomic defense induced by antisense TE transcription was also found in maize; silencing of the *MuDR* element involves transcription of *Mu killer*, which is the inverted duplicate of a partially deleted *MuDR* and induces heritable silencing through the small RNA pathway (Slotkin et al. 2003; 2005).

The best-studied and most suggestive link between TE derepression and speciation involves crosses between *Arabidopsis thaliana* and *A. arenosa*, which show postzygotic isolation mediated at least in part by proliferation of the pericentromeric *ATHILA* retrotransposon. Typically, *A. thaliana* ovules fertilized by *A. arenosa* pollen result in 95-100% seed abortion, and the reciprocal cross is impossible because *A. thaliana* pollen do not germinate on the *A. arenosa* stigma (Comai et al. 2000). Josefsson et al. (2006) demonstrated that seed abortion is significantly reduced when the *A. thaliana* female parent has higher ploidy than the *A. arenosa* pollen parent. In this cross, hybrid viability is correlated with the expression of only paternally derived *ATHILA* elements, which are more abundant in the *A. arenosa* (the paternal parent) genome than in *A. thaliana* (Josefsson et al. 2006). To explain this Josefsson et al. (2006) proposed the dosage dependent induction (DDI) model suggesting that increased relative maternal ploidy (i.e., dose) increases protection of the embryo and endosperm by balancing maternal suppressive factors with the paternal *ATHILA* copy number.

Since not all TE families are mobilized in the *A. thaliana* x *A. arenosa* cross, it remains unclear to what extent quantity and or specificity of repressors are important to hybrid inviability (Josefsson et al. 2006; Michalak 2009; Calarco and Martienssen 2011; Castillo and Moyle 2012). Furthermore, Martienssen and colleagues also suggest that both paternal and maternal factors may be involved (Slotkin et al. 2009; Martienssen 2010; Calarco and Martienssen 2011). Unlike animals, which only contribute small RNAs maternally, in *Arabidopsis* (and other angiosperms) both sexes contribute small RNAs that impact TE silencing. However, the two sexes produce distinct classes of small RNAs. Females produce 24-bp RNAs that interact with ARGONAUT9 in a manner reminiscent of the Piwi family - piRNA pathway in animals (Olmedo-Monfil et al. 2010). In males, pollen consists of three haploid cells - two identical sperm cells within an encompassing vegetative cell (McCormick 1993). TEs are derepressed via a regulated loss of DNA methylation in the vegetative nucleus and give rise to a distinct class of 21-bp small RNAs that are then passed to the sperm cells where they contribute to silencing their cognate elements (Slotkin et al. 2009). If it is necessary to have appropriate constituents from both the 21 and 24-bp small RNA pathways to silence TEs in hybrid offspring, the inviability of *A. thaliana* x *A. arenosa* hybrids may result from mismatches in suppression from either or both parental genomes.

Other examples that circumstantially tie TE derepression in plant hybrids to speciation include sunflower and rice. In sunflowers, three diploid species have arisen by ancient hybridization between *Helianthus annuus* and *H. petiolaris*. The hybrid species *H. anomalus*, *H. deserticola*, and *H. paradoxus* independently experienced large increases in retrotransposon content that are broadly consistent with the time of the species' origins (Welch and Rieseberg 2002; Schwarzbach and Rieseberg 2002; Gross et al. 2003; Ungerer et al. 2006; 2009). Interestingly, in five current natural hybrid zones between *H. annuus* and *H. petiolaris*, TE copy number in hybrid plants does not exceed the parental species values despite active transcription of the same TE families that are expanded in the three species derived from ancient hybridization (Kawakami et al. 2011). This finding suggests that post-transcriptional regulation currently limits TE proliferation in *Helianthus* hybrids. The fact that the three hybrid species

are each adapted to extreme environmental conditions is consistent with the ‘genomic shock’ and ‘epi-transposon’ ideas where TE proliferation in hybrids is promoted by a combination of biotic and abiotic stressors (in this case hybridization and harsh environmental conditions) upsetting the epigenetic defenses that normally keep TE activity suppressed (McClintock 1984; Wessler 1996; Lisch 2009; Zeh et al. 2009).

In rice, the genomic distribution and abundance of the miniature inverted-repeat transposable element (MITE) *mPing* differs within and between *indica* and *japonica* subspecies of *Oryza sativa* (Jiang et al. 2003), reflecting multiple rounds of differential amplification (Lu et al. 2012). Additionally, it has been shown in laboratory crosses that a hybridization signal provided by pollination with wild rice, *Zizania latifolia* remobilizes *mPing*, its supposed autonomous partner *Pong*, and at least two other TE families (*Tos17* and *Dart*; Shan et al. 2005; Wang et al. 2010). This suggests that bursts of TE proliferation in rice may be a consequence of hybridization; however, it remains far from illustrating a direct role in speciation.

MECHANISM II: MECHANICAL INCOMPATIBILITY

Rose and Doolittle’s (1983) focus on Mechanical Incompatibility dealt with two potential roles that TEs might play in hybrid infertility and inviability. First, rapid sequence turnover, particularly in heterochromatic repeats, could result in meiotic nondisjunction due to failure of homologous chromosomes to recognize each other during meiosis. Second, differential proliferation among chromosomes could disrupt necessary spatial relationships among nonhomologous chromosomes that are based on relative chromosome arm length (see Rose and Doolittle 1983). They concluded that there was little evidence for these types of mechanical isolation despite ample evidence for sequence turnover and proliferation. In fact they noted how little sequence homology was actually necessary for chromosomes to segregate properly. Somewhat ironically, the first “speciation gene” identified in animals, *Odysseus*, is now known to be a coevolutionary result of genomic conflict driven by the need to bind with rapidly changing heterochromatic repeats (see chapter by Phadnis and Malik in this volume); and this interplay between heterochromatin associated factors is emerging as a common cause of *Drosophila* incompatibilities (e.g., Brideau et al. 2006, Bayes and Malik 2009, Ferree and Barbash 2009, Cattani and Presgraves 2012).

Another way that TE activity might result in mechanical incompatibility is by generating structural variation (e.g., inversions, translocations, duplications, or deletions). Isolation due to chromosomal rearrangements could arise as a direct consequence of underdominance (i.e., lower heterozygote fitness than either homozygote) in heterokaryotypic hybrids. For instance, crossovers within inversion heterozygotes may result in gametes that do not contain a complete gene complement. If such crossovers were common, hybrids between populations or species with different inversions would be expected to show underdominance for fertility. A major difficulty with the potential for rearrangements to cause isolation directly is that fixation of an underdominant rearrangement is unlikely except in situations where genetic drift is strong (Walsh 1982; Lande 1985). If, on the other hand, there is no underdominance so that rearrangements are more likely to fix, then they are expected to have little effect on isolation.

Although direct responsibility for isolation seems unlikely, structural variants (particularly inversions) may indirectly facilitate isolation by reducing or eliminating regional

recombination near breakpoints in heterokaryotypic individuals (Rieseberg 2001; Noor et al. 2001; Hoffmann and Rieseberg 2008; Brown and O'Neill 2010; McGaugh and Noor 2012). Recombination plays a critical role in the shaping of integrated systems within species, forming adaptive peaks in the potential field of gene combinations and holding the species as a cohesive unit (Wright 1931; 1932; Gavrillets 2004). Reduced recombination facilitates the maintenance of linkage among genes involved in adaptive divergence and reproductive isolation (Rieseberg 2001; Noor et al. 2001; Navarro and Barton 2003). Under this scenario, mechanical isolation is only indirectly responsible for what is more accurately a genic model of speciation. The so-called “genomic islands of divergence” that arise in regions of low recombination only contribute to speciation when they contain factors contributing to reproductive isolation (Feder and Nosil 2009). For TEs to be implicated in speciation via this mechanism requires: 1) identifying TEs as the cause of inversion, and 2) showing that loci within the inversion cause isolation.

EVIDENCE FOR MECHANISM II

Structural Variation Caused by TE Activity

Besides normal transposition events, which depending on the type of TE, may or may not involve duplication, TE mediated structural variants arise when: 1) homologous TEs at different genome locations recombine (ectopic recombination), 2) when TE excision results in ectopic sequences being incorporated during double strand break repair (non-homologous end joining), or 3) when the ends from two TEs synapse and engage in complete or partial simultaneous transposition (alternative transposition; reviewed in Gray 2000; Feschotte and Pritham 2007b). There is abundant evidence that each of these are common causes of structural variation (Collins and Rubin 1984; Engels and Preston 1984; Lister et al. 1993; Lim and Simmons 1994; Walker et al. 1995; Hua-Van et al. 2002; Zhang et al. 2009; Xing et al. 2009; Quinlan et al. 2010; Guillén and Ruiz 2012).

In some cases TEs may occur near breakpoints as a consequence of inversion rather than a cause because they tend to accumulate in regions of low recombination. However, TEs are clearly causative in other cases; perhaps the best examples coming from *Drosophila buzzatii*, where Ruiz and colleagues have mapped members of the class II TE families, *FoldBack* (*FB*) and *hAT*, to breakpoints of several inversions that occur in natural populations (Caceres et al. 1999; Casals et al. 2003; Delprat et al. 2009; Guillén and Ruiz 2012).

Structural Variations Associated with Reproductive Isolation

Studies in *Drosophila* spp. (Noor et al. 2001; Machado et al. 2007a), *Sorex* shrews (Basset et al. 2008), *Anopheles* mosquitos (Michel 2006), *Rhagoletis* flies (Feder et al. 2003), and *Mimulus* monkeyflower ecotypes (Lowry and Willis 2010) all demonstrate that rearranged regions diverge more quickly than collinear ones, or maintain greater divergence in the presence of gene flow between closely related races or species. However, the association between islands of divergence and speciation is not necessarily straightforward, as patterns of

nucleotide differentiation are not sufficient evidence in and of themselves to infer a causal link with speciation (Noor and Bennett 2009; Turner and Hahn 2010). Additionally, regional differentiation may be maintained by selection even without chromosomal rearrangements (e.g., Turner et al. 2005; Harr 2006; Feder and Nosil 2009; Nadeau et al. 2012).

There are at least two examples where divergence in inversions has been tied to reproductive isolation. First, Noor and colleagues have mapped isolating barriers to inversion differences between *D. pseudoobscura* and *D. persimilis* (Ortiz-Barrientos et al. 2004; Ortiz-Barrientos and Noor 2005). These two species diverged within the last 500,000 years and are fixed differently for two inversions, but have experienced extensive introgression in other parts of the genome. Differences in cuticular hydrocarbons, mating preference, hybrid male sterility and inviability, and hybrid courtship dysfunction all map wholly or in part to the two fixed inversions (reviewed in Noor et al. 2001; Machado et al. 2007b; McGaugh and Noor 2012).

Second, Lowry and Willis (2010) discovered a geographically widespread inversion polymorphism responsible for local adaptation and prezygotic isolation in *Mimulus guttatus*. In a reciprocal transplant experiment wherein they isolated the effect of the inversion in nature by reciprocally introgressing into the genetic background of alternate ecotypes (perennial vs. annual) they showed that the inversion affects morphology, flowering time, survivorship, and prezygotic isolation.

A TE Induced Structural Variant That Causes Isolation

Clearly there is independent evidence for TE's role in both generating structural variation, and structural variation being tied to isolation. There is also at least one case where a TE induced variant is partially responsible for originating postzygotic isolation; the maternal effect dominant embryonic arrest (Medea) system in the red flour beetle *Tribolium castaneum*. Four Medea factors have been isolated from nature, but only 2 are stable in lab culture (M1 and M4; Beeman et al. 1992; Beeman and Friesen 1999). M1 is found in most regions of the world and has a selfish advantage when invading naïve populations because offspring of heterozygous mothers who do not receive a copy of M1 all die early in development (Wade and Beeman 1994). M4 has an even broader geographic range, and produces a very similar phenotype, but M1 and M4 do not cross rescue. The causative locus for M1 has been mapped to a 21.5 kb composite Tc-1 like transposon insertion containing several defective *Tribolium* gene duplicates (Lorenzen et al. 2008). The insertion occurs in the ~700bp intergenic region between the 3' UTR of two functional genes and while the mechanistic cause of the maternal phenotype remains unknown preliminary data show that the insertion may disrupt cis-natural antisense transcription that occurs in wildtype beetles (Demuth et al. unpublished data).

What makes Medea relevant to the present discussion of speciation is that offspring from crosses between M1 (or M4) and a second, hybrid incompatibility factor (H-factor), do not fully develop. H-factor is found widely distributed in India, and represents a strong postzygotic isolating barrier despite Medea and H-factor each producing viable, fertile offspring in combination with wildtype populations (Thomson et al. 1995; Thomson and Beeman 1999). Recently, H-factor was mapped to variation within the introns of an ecdysone receptor homolog, but the functional mechanisms underlying interaction between Medea and H-factor remain a mystery (Drury et al. 2011).

MECHANISM III: GENOMIC RESETTING

The last potential mechanism by which Rose and Doolittle suggested TEs might play a role in speciation involves their capacity to contribute regulatory sequences. Autonomous TEs encode the proteins and regulatory information necessary to catalyze their own transcription. There is now abundant evidence that proteins and regulatory sequences derived from TEs, have been exapted to perform functions for their host (Britten 1997; Feschotte 2008). Transposases in particular have been a recurrent source of “domesticated” genes. Because they are DNA binding proteins, typically with self-specificity, as a TE disperses throughout a genome it has the potential to “rewire” regulatory circuits if the transposase becomes domesticated (Cordeaux et al. 2006; Feschotte 2008). In addition to abundant evidence for isolated recruitment of functional coding and non-coding sequences originating from TEs, there is growing evidence for their role in large scale rewiring of transcriptional modules (Bourque et al. 2008; Kunarso et al. 2010; Lynch et al. 2011; Schmidt et al. 2012), but no evidence that we are aware of for this mechanism in speciation.

Despite a lack of evidence for this mechanism in its original formulation, the mechanistic details of genome defense against TE activity discussed above have several facets that could easily fall under the heading “genomic resetting” though it begins to blur the line with the genomic disease model. For instance, growing evidence shows that in the germline of plants and animals, safeguarding gametes and embryonic cells involves wholesale changes in the heterochromatin of “companion” cells such that TEs are derepressed in order to provide templates for small RNA that will go on to re-establish TE silencing in cells that form the offspring (Chambeyron et al., 2008; Slotkin et al. 2009; Calarco and Martienssen, 2011). This is genome resetting, or reprogramming, in a literal sense. Indeed the newfound interplay between small RNAs, TEs, methylation and histone modification has prompted a call for a chromatin model of speciation (Michalak 2009).

CONCLUSION

As we stated in introducing this chapter, we have learned much in the 30 years since Rose and Doolittle’s “Molecular Biological Mechanisms of Speciation”. However, in many respects TEs belong to the “dark matter” of genomes and their role in speciation remain obscure. Because of their repetitive nature they are typically viewed as a nuisance to genome sequencing projects, remaining in bins of unassembled “junk” reads. Surveying them individually poses its own challenges, so getting good estimates of variety and copy number among taxa requires significant effort and purposeful investigation. Given that the decades old search for “speciation genes” has provided few candidates and even fewer where early causation can be inferred, it would be premature to draw strong positive or negative conclusions about TEs role as causative agents in speciation. Additionally, since our ability to assay epigenetic mechanisms of genome defense (e.g., small RNA, methylation, histone modification) on a genome-wide scale in non-model organisms are still nascent technological advances, perhaps it is not surprising that we lack many strong examples. As our mechanistic understanding of TEs and ability to survey them improves, we fully expect to find additional evidence for the role of TEs in speciation.

ACKNOWLEDGMENTS

We would like to thank E. Betrán, and C. Feschotte for helpful comments and discussions about the manuscript. This work was supported by funding from National Institutes of Health grant #2R01GM065414-05A1.

Chapter 11

HYBRID INCOMPATIBILITY: ARE CELLULAR PROCESSES THE BATTLEFIELDS OF GENOMIC CONFLICT?

Norman A. Johnson

Department of Biology, Department of Environmental Conservation,
Graduate Program in Organismal and Evolutionary Biology,
University of Massachusetts, Amherst, MA, US

ABSTRACT

Recent studies suggest that much hybrid incompatibility results as a consequence of conflict between different components of the genome (genomic conflict). In this chapter, I argue that the battlegrounds for much of the conflict-driven hybrid incompatibility consist of various cellular structures and processes. These include the recombination machinery, centromeres and kinetochores, and heterochromatin and its associated proteins. I conclude with a call to integration between cell biology and evolutionary biology in the study of the evolutionary genetics of hybrid incompatibility.

1. HYBRID INCOMPATIBILITY

"The spread within a population of genes that may eventually induce isolation between populations is probably due to their properties other than those concerned with isolation." (Dobzhansky 1937, p. 258).

Hybrids between closely related species often have reduced fertility or viability, sometimes to the extent of being completely sterile or inviable (reviewed in Coyne and Orr 2004, chapters 7 and 8). These hybrids can also exhibit abnormalities in morphology (e. g., Wade and Johnson 1994), behavior (e.g., Noor 1997), and/or physiology (e.g., Willet 2011). Collectively known as hybrid incompatibility (HI), these fitness reductions and associated abnormalities, continue to draw the attention of evolutionary biologists. This attention arises in large part because hybrid incompatibility is a form of reproductive isolation, and thus central to speciation.

HI is also of interest because its evolution appears paradoxical: why would not being able to produce offspring be favored by natural selection? Both Darwin and Wallace weighed in on this puzzle (reviewed in Cronin 1991; Johnson 2008). Wallace thought there were circumstances where HI (notably sterility) could be favored by natural selection, but Darwin maintained that hybrid incompatibility was only a consequence of other adaptive or neutral changes (see Cronin 1991, for more information). Subsequent studies of HI have largely vindicated Darwin's position (Dobzhansky 1937; Muller 1942; Coyne and Orr 2004). With only rare exceptions (discussed in Johnson 2008; Turner et al. 2011), HI evolves as a by-product of evolutionary divergence, and not because of direct selection.

What, then, is the nature of this evolutionary divergence that underlies HI? At the start of the 21st century, that answer appeared to be that differences in ecological factors led to selectively driven changes in nascent species (Schluter 2000, 2009; Coyne and Orr 2004). This supposition was supported in part by ecological studies showing that divergent natural selection could lead to reproductive isolation (Nosil 2012). More support comes from a comparative study by Funk et al. (2006) showed that the amount of reproductive isolation between populations or species correlated with the extent of ecological divergence, once genetic distance was factored out. Finally, several genes connected to HI in *Drosophila* showed the signature of positive selection as revealed by the McDonald-Kreitman test (e.g., Ting et al. 1998; Barbash et al. 2003; Presgraves et al. 2003).

More recent studies challenge the generality of this ecological explanation for the evolution of HI. The discovery of new genes that contribute to HI and further analysis of previously studied ones suggest that few of these HI genes diverged due to standard ecological differences (Presgraves 2007; 2010; Johnson 2010). Instead, many of these genes appear to be related to conflict between different parts of the genome (Johnson 2010; Presgraves 2010; Mahshwari and Barbash 2011; Crespi and Nosil 2013).

2. CONFLICT-DRIVEN HI

"The unity of the organism is an approximation, undermined by these continuously emerging selfish elements within their alternative, narrowly self-benefitting means for boosting transmission to the next generation. The result: a parallel universe of (often intense) sociogenetic interactions *within* the individual organism--a world that evolves according to its own rules, as modulated by the sexual and social lives of the hosts and Mendelian systems that act in part to suppress them." (Burt and Trivers 2006, p. 475).

The evolutionary interests of different parts of the genome vary, and these differing interests lead to what is known as genetic or genomic conflict (Burt and Trivers 2006). Although genomic conflict has been recognized since the modern evolutionary synthesis of the middle-20th century (e.g., Ostergren 1945), its importance as an evolutionary force has been recognized only fairly recently (Burt and Trivers 2006). More specifically, various authors have proposed genomic conflict as an explanation for HI over the last thirty years (e.g., Rose and Doolittle 1983; Frank 1991; Hurst and Pomiankowski 1991), but these claims were generally dismissed by those studying HI (e.g., Johnson and Wu 1992; Coyne and Orr 1993). Additional data in recent years has led to a re-examination of the role of genomic conflict to the evolution of HI, and thus, speciation (McDermott and Noor 2010).

In a recent review paper, Crespi and Nosil (2013) coined the term conflictual speciation, and defined it as "the evolution of reproductive isolation as a byproduct of antagonistic selection among genomic elements with divergent fitness interests". Crespi and Nosil present conflictual speciation as one of the alternatives to ecological speciation, the process by which reproductive isolation evolves as a consequence of divergent natural selection (Schluter 2000, 2009; Nosil 2012). Both ecological speciation (Schluter 2000, 2009; Via and West 2009; Nosil 2012) and conflictual speciation (Johnson 2010; Presgraves 2010; Crespi and Nosil 2013; see below) are supported by several lines of evidence.

One line of support for the importance of ecological speciation comes from a meta-analysis by Funk et al. (2006). Prior studies had examined patterns of the accumulation of reproductive isolation between pairs of species in a variety of taxa including *Drosophila* frogs, butterflies, fish, birds, and plants (reviewed in Coyne and Orr 2004; Johnson 2006). These studies generally found an increase in indices of reproductive isolation with increasing genetic distance (a proxy for time). Funk et al. (2006) found that when genetic distance was factored out of the analysis, that species with greater ecological differences evolved more reproductive isolation between them than species with lesser ecological divergence. They then claimed that this result supports ecological speciation. Although this logic is sound, a closer examination of the data (Funk et al. 2006) shows that the correlation between reproductive isolation and ecological divergence is considerably stronger for premating reproductive isolation than it is for postmating reproductive isolation (i.e., HI). Thus, ecological speciation appears to be more prevalent for premating than for postmating isolation.

Many HI genes do show a signature of repeated selection based on McDonald-Kreitman (1991) and similar tests. Such a signature could arise from the selection associated with genomic conflict instead of ecological adaptation (Johnson 2010; Presgraves 2010). In fact, we would expect such signatures to occur more often when the selection involves conflict than when it involves ecological adaptation. The rationale is that conflict-associated selection is more likely to occur in repeated bouts than selection associated with ecological changes because conflict entails co-evolving units of the genome (Presgraves 2010; Crespi and Nosil 2013).

I argue below that conflict-driven HI involves cellular functions and processes. Thus, to understand the mechanics of HI, we need more studies of the evolutionary biology of the cell.

A surprisingly large number of genes or genetic regions involved in hybrid incompatibility are either heterochromatin or bind heterochromatin (reviewed in Johnson 2010; Johnson and Lachance 2012; Maheshari and Barbash 2011; Sawamura 2012). Heterochromatin is not an inert part of the genome; in fact, it plays several important roles including regulating gene transcription and chromosome segregation. Notably, chromosome segregation abnormalities can result from improper heterochromatin formation (Yasuhara and Wakimoto 2006).

One HI gene that is linked to heterochromatin is the *Odysseus* gene, a gene that is involved in the sterility of male hybrids of *Drosophila simulans* and *D. mauritiana*. It was one of the first hybrid incompatibility genes to be molecularly characterized, and was shown to contain a homeobox (Perez et al. 1993; Ting et al. 1998). Thus, it was reasonable to assume that *Odysseus* encodes a transcription factor, and the associated hybrid sterility arose from dysfunctions in transcriptional regulation (reviewed in Oritz-Barrientos et al. 2007). Recently, Bayes and Malik (2009) discovered that *Odysseus* has another role: its protein product binds heterochromatin, and inappropriate binding of heterochromatin appears to be associated with the hybrid sterility.

In this volume, Phandis and Malik discuss studies of *Odysseus* in further detail. Phandis and Malik (this volume) also discuss the HI gene *Overdrive*, a gene involved in both hybrid sterility and meiotic drive in hybrids between *Drosophila* species. While genomic conflict certainly has driven the evolution of *Overdrive*, the role (if any) of cellular processes for this gene is unknown.

Below I focus on genomic conflict and its possible relationships with HI genes in two arenas: recombination-associated genes (section III) and centromere/ kinetochore-associated genes (section IV).

3. PRDM9 AND OTHER RECOMBINATION-ASSOCIATION GENES

"The 'hotspot paradox' states that due to biased gene conversion, a hotspot tends to kill itself, nevertheless, there are many hotspots in extant genomes." (Wu et al., 2012, p. 2)

Some F1 male hybrid genotypes between *Mus musculus musculus* females and *M. m. domesticus* males result in complete sterility. Other F1 male hybrid genotypes are fertile, to varying degrees; a substantial part of that variation is due to what was called the *Hst-1* (*Hybrid sterility 1*) locus (Forejt and Ivanyi 1974; Mihola et al. 2009). Recent studies have shown that *Hst-1* is *Paired domain number 9* (*Prdm9*), which is also known as *Meisitz* (Meiotic gene with SET/PR domain and Zinc fingers) (Mihola et al. 2009; Flachs et al. 2012). Thus far, *Prdm9* is the only mammalian gene known to contribute to hybrid incompatibility that has been characterized at the molecular level (Mihola et al. 2009; Flachs et al. 2012); its sterility phenotype is manifest as meiotic arrest in the pachytene stage of meiosis I (Flachs et al. 2012, and references within). F1 males from the reciprocal cross (*M. m. d.* females x *M. m. m.* males) are fertile, but suffer from reduced fecundity, as compared to pure species males (Mihola et al. 2009; Flachs et al. 2012).

A recent transgenic study showed *Prdm9* can rescue fertility in sterile hybrid males and the rescue effect correlates with dosage (Flachs et al. 2012). The sensitivity to *Prdm9* varied across genetic backgrounds. Moreover, reciprocal hybrids (which are mostly fertile) are also sensitive to *Prdm9*. Interestingly, the hybrid incompatibility effect of *Prdm9* does not appear to be due to its own transcript (Flachs et al. 2012).

One of the roles of *Prdm9* concerns the regulation of recombination hotspots. In mammals, recombination events at the local scale are concentrated in regions referred to as "hotspots" (Paigen and Petkov 2010). Such hotspots often have associated short motifs (10-15 nucleotides), and recombination appears to involve the binding of proteins to the sequences associated with the hotspots. In addition to a SET methyltransferase domain (Ponting 2011), *Prdm9* also encodes a variable number of zinc finger domains (Segurel et al. 2011). These zinc finger domains bind preferentially to recombination hotspots (Paigen and Petkov 2010; Wu et al. 2012).

The exact mechanism by which *Prdm9* affects hybrid fertility is not yet completely worked out, but the number of zinc finger repeats in the protein is associated with the sterility phenotype (Mihola et al. 2009). It should also be noted that the SET methyl transferase domain methylates histones, and thus can alter chromatin composition (Ponting 2011).

Why would we expect genomic conflict to be involved in the evolution of *Prdm9* and other recombination-associated genes? The answer is related to what has been called the "hotspot

paradox" (Friberg and Rice 2008; Paigen and Petkov 2010; Ubeda and Wilkins 2011). Recombination hotspots induce double stranded breaks, and can cause biased gene conversion, with the result that the hotspots are converted into coldspots (Paigen and Petkov 2010). The paradoxical result is that hotspots cause their own destruction. Yet, hotspots exist. The apparent resolution of the hotspot paradox comes from recombination-modifiers like *Prdm9* that cause specific DNA sequences to be hotspots. Evolutionary changes in recombination-modifiers create new hotspots (Friberg and Rice 2008; Ubeda and Wilkins 2011). In this model, the conflict arises over the level of genetic recombination, with coldspots driving against hotspots and *Prdm9* and other recombination modifiers acting as modulators of the conflict (Ubeda and Wilkins 2011). Jeffreys and Neumann (2005) provide evidence showing that cold alleles are preferentially transmitted over hot alleles. This process is one akin to the Red Queen "arms races", where there is relative stability in the overall recombination rate, but a dynamic turnover of hotspots, coldspots, and sites within the recombination-modifiers (Ubeda and Wilkins 2011).

Consistent with this Red Queen model, the zinc finger domains of *Prdm9* are rapidly evolving in several lineages of mammals (Oliver et al. 2009; Ponting 2011). Additional evidence comes from dogs and their close relatives, which lack functionality in the zinc finger domain of *Prdm9* (Munoz-Fuentes et al. 2011). Associated with this loss of *Prdm9* function, the recombination hotspots are more stable in canids than they are in primates (Axelsson et al. 2012). Incidentally, there is no *Prdm9*-like mechanism for recombination hotspots in *Drosophila* (Heil and Noor 2012). Variation at *Prdm9* also affects genome instability (rearrangements) with some variants within humans being associated with varying risk for genetic abnormalities and non-disjunction (Berg et al. 2010; Borel et al. 2012).

Prdm9's binding sites explain only about 18% of the variation in mouse recombination (Wu et al. 2012, and references within). Thus, we should expect other proteins to also contribute to recombination hotspots. Some of these proteins may be candidates for HI genes. In a bioinformatic analysis, Wu et al. (2012) search for other modifiers of recombination. They looked for transcription factors that bind preferentially to hotspots. A Gene Ontology (GO) analysis reveals that these hotspot-binders were more likely to play a role in recombination, as well as in histone modification and other epigenetic functions (Wu et al. 2012). This study also pointed to a few candidate genes, one of which is *ZFX*, an X-linked gene that encodes a zinc finger domain. Interestingly *ZFX* appears to have spermatogenic function, and mutations in it in mice can lead to reduced germ cell number in both males and females (Wu et al. 2012). There are no known cases of *ZFX* contributing to hybrid sterility, but based on its features as a binder of recombination hotspots and spermatogenesis function, a logical place to look for genes involved in hybrid sterility is *ZFX*.

4. THE CENTROMERE AND ASSOCIATED STRUCTURES

"A central paradox in biology is that organisms must remain stable to maintain the integration of complex developmental and functional systems, but they must also adapt to accommodate changing environments" (Schwenk et al., 2009, p. 11)

As evidenced by the quote above, whole organism evolutionary physiologists recognize a tension between the competing needs of evolutionary flexibility (or evolvability) and stability (homeostasis). The same is also true with cellular structures and functions. One place where this

homeostasis/ evolvability tension is particularly acute occurs in the machinery used in cell division: the centromere and kinetochore structures (Burrack and Berman 2012). During mitosis and meiosis, sister chromatids are attached at the centromere. The kinetochore, which is assembled on the centromere, is a complex of proteins on the chromatids where the spindle fibers attach, allowing for the chromatids to segregate to different poles. Thus, these structures play crucial roles in chromosome segregation, a complicated and intricate process (Burrack and Berman 2012). If this process does not occur properly, a likely result is aneuploidy, a deviation from the standard component of chromosomes in a cell. Like mutations, aneuploidy can be advantageous in rare occurrences, it is much more often deleterious (ref).

The kinetochore can involve at least a hundred different proteins, some of which must interact with others in order to properly assemble the complex. Moreover, physiological changes can affect kinetochore assembly; thus, the process must be buffered against perturbations (Burrack and Berman 2012). Both centromeres and kinetochores can evolve rather rapidly, as seen by variation in features of these structures even among closely related species, and sometimes even within species. This diversity is reviewed in Burrack and Berman (2012).

Centromere DNA evolves at rates much higher than rates at other non-coding regions (Burrack and Berman 2012). At least some of the increased rate of evolution of centromeric DNA arises from genomic conflict, specifically the conflict that arises over asymmetries in female meiosis (Burt and Trivers 2006; Malik 2009). During meiosis in females, one of the four cells will become the functional gamete (the egg), while the other three are "dead end" polar bodies. There is, thus, intense competition for chromatids to get in the functional egg as opposed to the polar bodies, a process that is called centromere drive (Henikoff et al. 2001; Malik 2009). One mechanism by which drive could arise is by centromeres varying in how well they attract microtubules (Henikoff et al. 2001; Malik 2009).

The rest of the genome would have an evolutionary advantage to suppress such centromere drive (Burt and Trivers 2006). Heterochromatic proteins may thus evolve as drive suppressors, which is consistent with the rapid evolution of some proteins associated with heterochromatin (e.g., Vernack and Malik 2009). Interestingly, a large number of genes involved in HI either are centromeric heterochromatin or bind to it (Johnson 2010; Presgraves 2010). Thomas et al. (2009) also suggested that the recombination-associated HI gene, *Prdm9* (see section III), may modulate centromeric drive.

The kinetochores may also be involved in HI. Two nucleoporins (Nup) genes, *Nup 96* and *Nup 160* were found in screens for hybrid inviability between *Drosophila melanogaster* and *D. simulans* (Presgraves et al. 2003; Tang and Presgraves 2009). Recently, Sawamura et al. (2010) showed that *Nup160* also contributes to hybrid female sterility in this species pair. Nup genes are involved in the selective transport between the nucleus and the cytoplasm via the nuclear pore complex (NPC) (deSouza and Osmani 2009). *Nup160* and other Nups are also involved in kinetochore assembly (Zuccollo et al. 2007) An additional line of evidence linking Nup genes to genomic conflict is the similarity between Nups and the *SD* segregation disorder system in *D. melanogaster* (Presgraves 2007).

5. A CALL FOR THE EVOLUTIONARY GENETICS OF THE CELL

"Must we geneticists become bacteriologists, physiological chemists and physicists, simultaneously with being zoologists and botanists? Let us hope so." (Muller 1922, p. 50)

Ninety years after Muller's remarks, let us now hope that evolutionary geneticists interested in hybrid incompatibility become cell biologists, along with all of the other hats that they wear. Let us also hope that cellular and molecular genetics interested in sterility also become evolutionary biologists. Hybrid incompatibility arises when the cellular processes break down when diverged genomes come together in the same cell. An understanding of how the cellular processes work, and how they can break down, appears ever more important to understanding hybrid incompatibility.

As shown above, many of the HI processes appear to be associated with genomic conflict. However, genomic conflict is not always involved. For instance, the processes of dosage compensation and Meiotic Sex Chromosome Inactivation (MSCI), which are related to the hemizyosity of sex chromosomes in the heterogametic sex, appear to play a large role in HI (Johnson and Lachance 2012). Yet, these processes are probably unrelated to genomic conflict. Ecological adaptation and compensatory processes also contribute to HI. Still, genomic conflict looms large. A detailed understanding of the cell will likely shed light on how these evolutionary processes lead to HI.

Chapter 12

PROCESSES IN ORGANIC AND CULTURAL EVOLUTION

Börje Ekstig*

Department of Education, Uppsala University, Uppsala, Sweden

ABSTRACT

In the present work, I give an all-embracing macroevolutionary perspective on processes of the evolution of life and culture on earth. First, I investigate a complementary form of natural selection that diverges from the traditional form in that it is acting independently of the external environment. This form of natural selection is found as a result of a mathematical analysis of the conditions for population growth. I extend my investigation as well to other evolutionary processes than the organic, such as the evolution of human language and the evolution of science, thereby suggesting other possible forms of underlying explanatory processes.

I examine the concept of complexity and show that it implies new insights into the ways natural selection has been acting in forming the evolutionary and developmental processes. Especially, complexity is found to be growing in an accelerating mode, a process that is explained as the combined result of natural selection and a self-reinforcing feedback process.

The use of the concept of complexity opens the possibility of construction of a new form of a Tree of Life, which, in contrast to traditional forms, combines complexity and time. Such an illustration of the evolutionary process explains the observation that most species live without great changes over vast periods of time. For species at the highest level of complexity there is no competition from species at still higher levels and these species can therefore, if conditions are beneficent, form new species at still higher levels. The process explains the emergence of new species and the general trend of evolution towards cumulatively higher complexity levels.

The cumulative addition of species with successively higher complexity implies that the latest appearing species is the one of the highest level of complexity. At present, this species is the human species.

INTRODUCTION

Individual Development and Evolution

Life is fantastic. To me it has always been irresistible to ponder upon the seemingly highly improbable course of events that has resulted in the appearance of mankind on earth and the likewise unfathomably long time during which this very process has incessantly been advancing. Equally enigmatic to me seems the marvellous developmental process of an animal or a human being, merely arising from the molecular genetic code, inherited from the long and unbroken chain of individual developmental courses ever since the dawn of life. In addition, it is to me the highest intellectual challenge to try to understand the intricate coupling between these two processes. Indeed, this is part what this work is about.

All the way during the course of evolution, natural selection is by the majority of researchers considered as the key mechanism. In this selection process, competition between organisms has been a decisive factor. Highly chaotic external factors have formed the underlying conditions for this contest in which natural selection has appointed the winner. The competition may have been about mates and food, as well as about capability to handle social life and the impact of diseases, predators and climate. Thus natural selection gives rise to a population's adaptation to its environment, thereby producing the enduring though irregular evolutionary changes. Due to the irregular nature of these external conditions it has been difficult, as testified by the history of the science of evolution, to find an all-embracing pattern and direction of evolution at large.

It is important to notice that the genetic material, the DNA, doesn't determine the evolutionary process. Instead, the DNA-molecule gives the plan for the individual's growth and its realization in the building up of an embryonic and juvenile individual creature. In the present work, I'm not entering the field of molecular biology – rather I discuss the macroscopic aspects of development and its evolutionary outcome.

A common notion of evolution seems to be to regard it as an extended sequence of adult organisms sustaining successive transformations due to natural selection. However, such a notion encompasses limited truth only. A central tenet forming the basis of the present thesis is that *natural selection primarily is acting on the developmental process* of individual growth and that *the process of evolution above all proceeds as a result of insensibly small and continuous modifications in the development programs* of living organisms, modifications having during the long extent of time given rise to the vast diversity of life on our planet.

This view is by no means new. It is expressed, for instance by Richard Dawkins, in saying that “evolutionary change is change in genetically controlled processes of embryonic development, not literal change from adult form to adult form (Dawkins 2004 B p. 200), and furthermore “that we have to understand development before we can speculate constructively about evolution” (ibid. p. 201). These aspects of development indicate the existence of some kind of relationship between development and evolution; a notion that has caused a long and engaged discussion ever since Darwin's discoveries.

In the current work, I present my own discovery of a concrete manifestation of this relationship and my interpretation of it as well as some far-reaching outcomes of the discovery.

The Problem of Evolutionary Change

In a tradition that harks back to antiquity, living organisms have been seen as arranged in a hierarchical order, thus placing the most simple at the lowest level and the more advanced higher up. This principle was developed without any time dimension, because the world with all its organisms in their present shape was thought to have been created at one and the same occasion. During the end of the eighteenth century, observations of successive temporal changes of organisms became impossible to deny, a notion that got its fulfillment by Charles Darwin in his explication of this successive change, an explication that, after unprecedented turmoil, finally became accepted by the scientific community. As we know, Darwin called his principle natural selection and the process of temporal change became called evolution.

Then however, the idea of hierarchical order came to be considered as obsolete and became abandoned. This is by and large the situation of today's scientific conception of the evolutionary process, even if there are attempts to revitalize the notion of hierarchical order. Thus Daniel McShea (2001) has argued that an increase of the complexity of organisms in evolution can be measured on a hierarchy scale. In the present work, I intend to show the high explanatory possibilities of arranging organisms in a progressively rising complexity scale.

But the situation isn't that easy because most organisms show only marginal changes over long periods of time. How then, as one may ask, to explain this observation by means of natural selection, supposedly being acting on behalf of the great variations in the external conditions that doubtlessly have occurred? And what's more, how to explain the fact that the oldest organisms of today, that is to say those having been exposed to natural selection for the longest time, still retain their archaic characteristics?

Actually, in the beginning of the nineteenth century, Lamarck pondered over this enigmatic observation already when the very idea of evolution was quite new and even before Darwin discovered the principle of natural selection. He asked how we still can see the complete hierarchy of living organisms today, if the active power of nature compels life to mount steadily up the chain of being. Why haven't all living things raised themselves to the same level as man? In his broad exposition of the history of evolution, Peter Bowler (1989 p. 85) has called attention to Lamarck's thought-provoking conundrum. Although much of Lamarck's views now are obsolete, I find his questions still challenging and my intention with the present thesis is to suggest an answer.

The reason for the scientific denial of a hierarchical order of organisms is obviously a lack of means by which to identify and measure such evolutionary levels. Such identification requires a measure of evolutionary progress, a measure that has turned out to be difficult to find.

However, there is a vast literature aiming at a solution of this deficiency. The most frequently suggested candidate for a concept to be used for the assessment of evolutionary progress is complexity. Before a discussion of this concept, I suggest that we prepare ourselves by making acquaintance with a couple of research fields associated to the evolutionary process.

Aim

The aim of the present work is to examine natural selection and its impact on the macroevolutionary process of life and human culture. Special attention is given to my discovery that natural selection in certain situations is acting independently of the external environment. The aim is furthermore to examine the concept of complexity, a concept, as is my intention to show, having great explicatory power for our understanding of the evolutionary process at large. Especially, I analyse the impact of a feedback process in complexity, a mechanism that I suggest as a complement to natural selection. I finally examine to what extension the discussed processes of biological evolution are applicable to human cultural evolution.

Evolutionary Developmental Biology

As I already have emphasized, my main view is to see evolution as the result of changes in the developmental course of individual creatures – by no means a new view. It is given attention in a special theory called Evolutionary developmental biology (*Evo-devo*). In his introduction to *Evo-devo*, Wallace Arthur (2011 p. 28) states that development is both a source for, and a result of, evolutionary change.

Likewise, in his emphasis on the genetic background, Sean Carroll accentuates that the evolution of form occurs through changes in development (Carroll 2005 p. 4) and that molecular changes contribute substantially to organismal adaptation (Carroll 2008). In his summary of *Evo-devo*, Gerd Müller (2007) states that this field explores the relationships between the processes of individual development and phenotypic change during evolution. Müller discusses how developmental systems have evolved and probes the consequences of these changes for organic evolution. He contends that *Evo-devo* aims at explaining how development itself evolves and how the developmental processes are formed by the interplay between genetic, epigenetic and environmental factors.

Unfortunately, the embryonic development of ancestral animals is not available for observations – they are not fossilized – and therefore conclusions regarding evolutionary trends of developmental changes are difficult. It seems that this difficulty to some degree is surmounted by the study of invertebrates. Thus Tills et al. (2011) have performed studies of snails taking advantage of the fact that snail embryos have benefits over those of vertebrates as they allow the study of the continuous developmental process.

Some authors point out that modifications in early embryos are very uncommon because of their supposedly profound effects on subsequent developmental events (Raff and Wray 1989). This view is even more clearly expressed by Brian Hall (2002 p. 13), suggesting that early development is immune to change or, if altered, would so drastically deflect subsequent development that early changes would be lethal or actively selected against. Yet, there is a type of changes that are not impeded by this obstacle.

Thus, Kalinka and Tomancak (2012) contend that many changes in early development result in increase in the tempo of embryogenesis and a shift from late to early-patterning processes; a view studied in the field of heterochrony. These remarks are of high significance for the continued analysis in this work.

Heterochrony

As emphasized in the field of Evo-devo, modifications of the developmental programs of growing creatures provide an important entrance to the understanding of evolution. A special kind of such modifications is temporal displacements of the formation of developmental traits, a phenomenon called *heterochrony*. Central contributions to this field of research are given by Stephen Jay Gould's (1977) classical *Ontogeny and Phylogeny*, by McKinney and McNamara's (1991) *Heterochrony* and by Rudolf Raff's (1996) *The Shape of Life*.

In his summary of heterochrony, Kenneth McNamara (2002, 2012) defines this process as a change of timing or rate of development relative to the ancestor. He states that heterochrony takes the form of both increased and decreased degrees of development. He also recognizes that genes regulating embryonic or larval development play a major role in evolution. These genes are the targets of mutations causing heterochronic change in phylogeny. A link between evolution and development is formed by the inherent directionality in evolutionary trends also occurring in organisms' development. McNamara concludes that also human features are moulded by the all-pervasive influence of heterochrony. Our overall large body size, relatively large legs, structure of our pelvis, enlarged cranium and brain, and even our big feet can be seen as resulting from heterochronic processes. As Raff (1996 p. 267) points out, studies of heterochronies have predominance for late development, but he stresses that heterochronies in early development have been found to be as prevalent as in late development. I would here like to remark that all heterochronic changes are more or less tacitly assumed to be formed by natural selection.

In the present work, I restrict the discussion to two simple forms of heterochronies – condensation and terminal addition. *Condensation* means the successive shortening of the interval of time needed for the shaping of each specific trait in the developmental process of individual creatures, a process causing displacement to earlier emergence of subsequent traits, a process called *acceleration*. Thus acceleration is caused by condensation and I therefore focus the discussion on condensation.

It should be emphasized that condensation, like other heterochronic processes, is a process expressed both in ontogeny and phylogeny, thus forming an issue for Evo-devo. One representative of this field of research maintains that when comparisons are made between very different levels of complexity, the emerging pattern is broadly recapitulatory, although only in a very imprecise way, in the sense of recapitulating levels of complexity rather than precise morphological details (Arthur 2002). It is interesting to note that Arthur includes complexity in his discussion, a concept that is central in the present thesis as well and will be analysed in forthcoming sections.

Terminal addition means the emergence of new traits with new functions at the end of the maturation period. One may think that terminal addition cannot be included in a strict definition of heterochrony since it means no change of timing or rate of development of existing early organs. Nonetheless, for instance McKinney and McNamara (1991) include it in their abundant terminology. They argue that much of the overall pattern of evolution can be explained by terminal addition and that one particularly important arrow of evolution, that of increasing complexity, seems to owe much of its existence to this process (ibid. p. 381).

Terminal addition occurs near the stage of maturity and is explained by the traditional interpretation of natural selection. An addition of a new trait is of course possible only on behalf of its reproductive advantage in the prevalent environment. Otherwise it wouldn't be inserted.

Terminal addition causes prolonged generation time owing to the insertion of novel traits at the end of the juvenile period. Such novel traits can lead to the emergence of new species and in this way terminal addition explains the diversity of life (*ibid.* p. 381). It must in this context be mentioned that after the stage of maturation great changes are rare because after reproduction, the fate of the adult animal has no bearing on the genes of its offspring. Of course, this rule is not absolute in the case of the adult's caring of its offspring. Furthermore, it isn't abrupt for iteroparous species.

The two processes of condensation and terminal addition result in opposite evolutionary trends; condensation results in shortening of the time from conception to adulthood, i.e., a shortening of generation time; terminal addition on the other hand prolongs maturity time, i.e., it increases generation time. A common notion, as Stephen Jay Gould (2002 p. 367) mentions, seems to have been that new stages cannot be added indefinitely to the end of previous ontogenies, lest growth of adulthood take untold years to reach completion. Some process must therefore, as it is thought, produce general speeding-up of development, leaving time at the end for novel features. Such a view, I think, implies evolution to embrace an element of intentionality, a view that must be resolutely rejected. An important goal of the present work is to explain the speeding-up of development in a scientific way.

As to heterochrony in general, it maybe isn't that all-pervasive as McKinney and McNamara contend. Thus Rice (1997) proposes that although heterochrony has become a central organizing concept relating development and evolution to each other, it can only accurately describe a small subset of the possible ways through which ontogeny can change. The somewhat bewildering nomenclature of heterochrony is meaningful only when there is a uniform change in the rate or timing of the ontogenetic process, with no change in the internal structure. In the present thesis, such a uniform temporal change without change in the internal structure forms a basic principle.

As mentioned above, there is a generally expressed contention that changes of traits in early development would so drastically deflect subsequent development that such changes might be lethal. But a change restricted merely to an increase in the tempo of the shaping of a trait, without change of internal structure, wouldn't change its function and therefore wouldn't be prohibited.

This is what characterizes the process of condensation. But there is another important consequence of this conclusion. If there is no change of function, natural selection has no alternatives among which to choose. How then to explain condensation? It seems that we have to examine the very process of natural selection somewhat closer.

ENVIRONMENT-INDEPENDENT NATURAL SELECTION

Population Biology

In his study of population biology, Stephen Stearns (1992) points out that a shortening of generation time is beneficial for the population growth because it increases its chances of surviving the often-risky juvenile period. A higher number of individual creatures will reach maturation and get the possibility to contribute to reproduction. In addition, a shorter generation time implies more frequent occasions of reproduction over time.

Therefore, these double advantages generate a selection pressure on all developmental traits to develop as rapidly as possible with retained functionality. Such a selection may give rise to a shortening of developmental traits once they have been established. We recognize this shortening as condensation.

There is simultaneously also a benefit of the opposite process – the prolongation of generation time. A delayed maturity, as Stearns points out, may imply greater size and a higher quality of the offspring, which leads to higher initial fecundity. This process, I maintain, is only occurring at the end of maturity time as terminal addition, since great changes of early developmental traits often are deleterious. Such terminal additions are explained by the traditional interpretation of natural selection.

Thus, there are two counteracting processes influencing generation length; one causing its shortening, associated to condensation of developmental traits, the other causing its prolongation, associated to terminal addition. An important contention of the present analysis is that these two processes are acting independently of each other. Hence, even if a species prolongs its generation time by means of terminal addition, its developmental traits may nonetheless be subject to condensation, implying that the actual change of generation time is the total result of both processes. In the majority of cases, the prolongation dominates but an assessment of the contribution of each of the processes seems difficult.

As we may conclude so far, there is a selection pressure on all developmental traits to develop as rapid as possible. An important question is now if the traditional form of natural selection is sufficient for explaining such a shortening because, as I already have pointed out, if there is no change of function, natural selection gets no alternatives among which to choose. One may thus conclude that condensation is invisible to natural selection, at least in its traditional interpretation. There is need for a more detailed analysis.

A Mathematical Analysis

The question is if the traditional form of natural selection is sufficient to explain condensation of developmental traits. I suggest an investigation of this question by means of a simple mathematical analysis. In this investigation, I examine the combined impact of reproduction, survival, and generation length for the growth of a population. Reproduction is associated to the ability to attract mates, to the size of the litter, and to the feeding and defending of the offspring, and is primarily of importance at the transition from one generation to the next. Survival is associated to the ability to catch prey and/or to avoid predators, to have good digestion, to have sensitive senses, to behave conformingly in the current social framework, and is primarily of importance during the lifetime of individual creatures. I examine by means of a mathematical analysis the impact of reproduction and survival on the growth of population size for different generation lengths.

Suppose that we have a population of which the fraction s survives every year. Then, if the generation time is g , the fraction of the initial number of the population at the end of a generation is s^g . We next suppose that the level of reproduction at the end of each generation will increase or decrease the size of the population by the factor r .

At the onset of a new generation the population size has thereby, due to the two factors r and s , changed to rs^g .

The number of such changes after time t is the number of generations during this time, which is t/g . Then the total number of individuals N in the population after time t will be

$$N/N_0 = (rs^g)^{t/g} \quad (1)$$

Where N_0 denotes the size of the population at the beginning of the studied period. We examine the impact on population size for different values of the three variables r , s , and g . Calculations are performed by means of numerical examples for four different cases.

Case 1. $rs^g > 1$; The population increases.

Case 2. $rs^g = 1$; The population is stable.

Case 3. $1 < r < s^{-g}$; The population decreases.

Case 4. $r < 1$; The population decreases.

I calculate the growth of the population N/N_0 by means of formula (1). The values of the parameters r and s are chosen for clarifying illustrations of three of the four cases (Case 2 is trivial since the size of the population is constant). In each case the growth of the population over generations is calculated for two different generation lengths and the result is illustrated in Figure 1.

This result is understood in the following way. The annual survival factor s , since always less than one, reduces the population, a reduction that is compensated for at the occasions of reproduction with the factor r at the end of generation time g .

Figure 1. (Continued).

Figure 1. The graphs of Equation 1 shown for some illustrative values of the variables r , s , and g .

In Case 1, the graphs show that the size of the population will grow faster for a shorter generation time. In this case the environment is beneficial for population growth implying that the total reduction at the end of each generation time is exceeded by the reproduction and if generation time is shortened, the number of annual reductions falls and the number of occasion of reproduction increases, both factors of which contribute to more rapid growth of the population size over time. This means that a shortening of generation time is beneficial for the growth of the population and hence there is a selection for shortening of generation time.

In Case 2, the reproduction constant at the end of generation time balances the annual reductions and the population is stable. In this case shortening of generation time is neither beneficial nor deleterious for the population. Yet, in this case the three parameters must have very special values for satisfying these conditions, which seems quite improbable, especially

as the features are stretching over time. Therefore, due to the natural variation of r and s , the conditions will very soon change to either Case 1 or Case 3.

In Case 3, the graphs of the formula show that the size of the population will decrease slower for a shorter generation time. In this case the reproduction at the end of generation time cannot fully compensate for the sum of annual reductions and the population size will decrease over time. But if generation time is shorter, the number of the annual reductions falls and the occasions of reproduction will be more numerous. Since the reproduction factor is bigger than 1, both these circumstances result in slower decrease of population size as testified by the graphs. Therefore, even under these harsh circumstances, a shortening of generation time is beneficial. This is an especially important implication of the mathematical model that, I think, hardly could have been intuitively anticipated. It clarifies the general selection pressure for shortening of generation time even in a deleterious environment. Together with Case 1 one can conclude that there is *a selection pressure for shortening of generation time, and therefore also for condensation, whether the environment is beneficial or deleterious*. Therefore the traditional interpretation of natural selection as being coupled to the external environment seems insufficient in explaining condensation and that there is an environment-independent form of natural selection responsible for the condensation of developmental traits.

If extended over a long time, this situation of course leads to extinction, a disaster however being postponed by the slower decrease of population size. In this way the population raises its chances of survival until less perilous external conditions appear or until it by means of ordinary natural selection has got time to adapt to the hostile environment. Because extinction is a far from infrequent occurrence in the history of evolution, the proposed process of shortening of generation time, I think, isn't without importance since one may think that a species despite hard external conditions in such critical periods may have avoided extinction by means of this process.

One should here remember that in the above discussion of condensation we concluded that condensation is invisible to natural selection, at least in its traditional interpretation because, since condensation implies no change of function of a trait, natural selection has no alternatives to choose amongst. This conclusion is, as we can see, concurrent with the result of the calculation, which shows that condensation actually can be independent of the environment. Still, I think one shouldn't abandon the process of natural selection when it is about condensation, just that it is of a form that is environment-independent. Because of this independence of the haphazardly varying external conditions it seems possible, maybe even plausible, that condensation could exhibit some degree of regularity.

In Case 4, the graphs of the formula show that the size of the population will decrease faster for shorter generation time.

In this case the low value of the reproduction constant adds to the decrease coming about by the small survival factor, implying that the population size will suffer a successive decrease. But in this case, as the analysis shows, the population decreases faster in case of shorter generation time. Therefore there is a disadvantage of a shortened generation time. The situation leads to extinction if not interrupted by a change to a higher value of the reproduction constant, thus bringing the population to the conditions of some of the former cases. Therefore species having in fact survived over time cannot have been applying the conditions of the fourth case except for short periods of time and therefore this case doesn't contradict the general selection advantage of shortened generation time for normal, long living species.

The main result of the mathematical analysis shows that, when a population is increasing, there is a benefit of shortened generation time. However, even if the population is decreasing as in situations when the external environment is moderately deleterious, there is a reproductive advantage of shortened generation time as well.

Hence, as the result of the theoretical analysis shows, the selection for shortened generation time is independent of the external conditions. This means, I claim, *that there is a form of natural selection that is independent of the external environment.*

One may perhaps dare to say that the tendency for shortened generation time is an inevitable characteristic of living creatures. I will in a coming section demonstrate an empirical support of this conclusion. As we see, this result is at odds with the traditional interpretation of natural selection according to which evolutionary changes are seen as adaptations to the external environment.

However, in the case of the selection pressure for shortened generation time, I cannot identify any possible feature in the environment to which condensation could be an adaptation. Therefore, natural selection in the adaptationist interpretation isn't applicable. Instead, as I have demonstrated, condensation is explained as a result of a form of natural selection that is independent of the external environment. This conclusion is concurrent with the conclusion as posed above, implying that condensation of developmental traits occurs without change of their function, and that therefore natural selection has no alternatives among which to choose.

Richard Dawkins (2004 B, p. 88) mentions the notion of evolutionary change *per se*, and I suggest one may use this idea and state that environment-independent natural selection is a process that, as opposed to adaptive change, might be characterized as evolutionary change *per se*. I think that this general notion can be meaningfully used in a comprehensive description of evolution.

An Application to Bacteria

The result of the analysis in this section is primarily of theoretical interest though I can think of an application regarding the growth of bacterial colonies. In a high-nutrient environment a population of bacteria increases and there is a selection for shorter generation time according to Case 1. In a situation of depleted nutrients or exposition to antibiotics, the population may decrease. At the application of antibiotics to pathogenic bacteria, the result of Case 3 is especially interesting, implying as it does a selection pressure for shorter generation time and a postponement of eradication under the conditions of moderate population decrease. The bacteria then have a somewhat prolonged time for adaptation to the antibiotics thus getting an opportunity of developing resistance. It is therefore important that the antibiotic treatment is given as a high dose therapy so that the decrease of the bacterial colony is fast enough to enter Case 4. The vital importance of a complete extinction of pathogenic bacterial colonies is already well understood though I think the present result gives additional emphasis to the importance of high antibiotic therapy.

As I already have pointed out, the tenet of the present work is that evolution proceeds as a result of the continuous changes in developmental programs of living organisms. After the above analysis of the developmental process, I continue by examining the coupling of the developmental process to that of evolution.

DEVELOPMENT AND EVOLUTION

The Relationship between Development and Evolution

There has since long been noticed that vestiges of old evolutionary stages can be observed in the embryogenesis of present-day individual organisms, observations that have been subject to enduring discussions related to the idea of recapitulation (for a comprehensive survey, see Richards 1992). These discussions were intense in the second part of the nineteenth century, but since they seem not to have given any satisfactory conclusion they have faded out. In the present work I revitalize the principle of the concept but avoid the term recapitulation because of its bad reputation.

I have been criticised for dealing with this connection, which by most biologists is considered an obsolete and abandoned idea. I must therefore try to make myself very clear, especially, as it's my conviction, that the connection gives a possible key to a deeper understanding of the evolutionary process. In addition, the connection constitutes the main empirical support of present work.

The interpretations of the observed vestiges have mostly been restricted to morphological and anatomical features within the field of biology. When I also included cultural features of the human species in the analysis, I discovered a conspicuous pattern, indicating a relationship between the developmental process of a modern individual human being and its evolutionary history. This pattern is depicted in Figure 2.

The pattern as revealed in the diagram of Figure 2 makes the notion of a relationship between development and evolution more concrete. As we can see, the pattern to a large extent comprises human cultural traits as well. Otherwise, the regularity would never have been disclosed and this, I think, is why biologists didn't discover it.

As we can see, the diagram reveals a concrete connection between development and evolution or, as used to be said, between ontogeny and phylogeny. Darwin himself observed and discussed this relationship as we can see in the following quotation:

I shall attempt to show that the adult differs from its embryo, owing to variations supervening as a not early age, and being inherited at a corresponding age. The process, whilst it leaves the embryo almost unaltered, continually adds, in the course of successive generations, more and more difference to the adult. Thus the embryo comes to be left as a sort of picture, preserved by nature, of the former and less modified condition of the species. This view may be true, and yet may never be capable of proof (Darwin 1859 p. 338).

The observation of such a relationship has been subject of a vigorous though bewildering discussion during the later half of the nineteenth century. Ernst Haeckel, known as a forceful supporter of Darwin's theory, stated the phrase "ontogeny recapitulates phylogeny," also known as the biogenetic law.

One of Darwin's great contributions, besides that of natural selection, is the concept of common ancestry. In one of his notebooks from 1837, i.e., one year before his discovery of natural selection, one can find a rough drawing showing this principle (Darwin 1837). It's interesting to note that it was probably not a direct observation of the phenomenon of evolution that gave him this brilliant idea but rather the study of embryos.

As Carl Zimmer (2002 pp. 316-317) points out, Darwin acquainted himself with studies of embryos of gorillas and chimpanzees and saw conspicuous similarities. Bone for bone, they are almost identical. As human embryos develop, they pass through virtually identical stages as gorillas or chimps. Only relatively late in their development do they start to diverge, taking on different proportions. These similarities, Darwin argued, were signs that apes and humans descended from some ancient common ancestor.

Figure 2. Individual development versus evolution of the lineage of man. The horizontal axis gives evolutionary time measured backwards from the present point of time. The vertical axis shows the individual age. Both scales are logarithmic. References to and discussion of the traits that are included in the diagram are given in my previous publication of the pattern (Ekstig 1994). This version of the diagram was published and further discussed in Ekstig (2007, 2010 A, 2015).

In looking at Darwin's principle of common ancestry from the perspective of developmental programmes, one may conclude that species having deviated from a common lineage share the same developmental course up to the stage corresponding to their divergence, a principle called *Spencer's theorem*. McKinney and McNamara (1991 p. 390) express this observation in saying that the more closely related two groups are, the more similar their ontogenies, and the later their ontogenies diverge.

Let me also refer to a remark on this issue made by Dawkins who reminds us that organisms, including human beings, form overlapping sequences of generations in which each generation exhibits a close resemblance to its progenitors. He then suggests an expressive metaphor: "Everything about a modern animal, especially its DNA, but its limbs and its heart,

its brain and its breeding cycle too, can be regarded as an archive, a chronicle of its past, even if that chronicle is a palimpsest, many times overwritten.” (Dawkins 2004 A p. 23) (A palimpsest is a manuscript page from a scroll or an old book that has been overwritten and used again.) In this metaphor, the DNA has a special weight because, as we know, the DNA is copied over and over again, with only small modifications, over many generations.

What makes the evolutionary process so complicated is a double causality. Evolution proceeds as a result of modifications in the development programs of living organisms and the development course recapitulates traits that are consecutively added during the evolutionary history. This mutual causality has come into being at the construction of the straight line in Figure 2.

When considering the diagram in Figure 2, I would like to emphasize that the traits forming the pattern are the same, whether appearing in an ancient ancestor or in a modern organism. Thus for instance, the three forms of kidneys, pronephros, mesonephros, and metanephros, are identical, at least as seen to their function, in the ancient reptile and in a modern human being. Of course, we cannot observe the ancient reptile but, as is generally observed, the embryonic organs don’t change much over evolutionary time, and we may therefore conclude that in today’s reptiles, the kidneys are the same as they were in the ancient reptiles. This is supposed to be valid for all traits in the diagram. By means of this reasoning, I conclude that the similarities giving rise to the biogenetic law can scarcely be said to be similarities at all because instead, with respect to their function, they are identical. Consequently, there is one and only one point for each trait in the diagram, though given two separate dates for its appearance.

What really is enigmatic, though, is the existence of such a regular pattern over such a great part of the evolutionary process, actually over all the time of animal evolution. Of course, this regularity insists upon an explication, especially as the process of evolution is supposed to be driven by natural selection depending on the highly irregular external contingencies that certainly have been prevailing all over this long time. Step by step, I will develop an explication of this conundrum.

The straight line invites to two ways of interpretation. The first concerns condensation and the second concerns complexity.

We first discuss condensation, the assessment of which is obtained by means of a mathematical analysis of the line.

The Regularity of Condensation

The straight line of course invites to a mathematical analysis. The equation of line is

$$\ln t_o = C_1 - C_2 \ln t_p \quad (2)$$

where t_o and t_p denote the developmental (ontogenetic) and evolutionary (phylogenetic) age of each trait, respectively. The values of dimensionless constants are determined by the scales on the axes yielding $C_1 = 5.12$ and $C_2 = 0.39$.

Due to the fact that the evolutionary timescale in the diagram of Figure 2 starts at the present point of time and displays time in the negative direction, the position of each particular event will be displaced to the left as time proceeds and, because of the fact that the time scale

is logarithmic, this displacement per unite time as seen in the diagram will appear smaller the higher the age of the trait.

Then the line wouldn't be linear except for the present point of time, which is a highly unsatisfactory feature. Instead it is reasonable to assume that the line reflects a general characteristic of life and not just an accidental coincidence of the present point of time, because, of course, our understanding of the evolutionary process cannot rely on the presumption that the present point of time has a special status in the evolutionary process.

However, there is a possibility that the linearity of the pattern is preserved over time if one assumes that the points are displaced downwards towards earlier developmental appearance simultaneously as they are moving to the left due to the increasing age of each trait with time. In accepting this, as I claim, highly reasonable assumption, one gets not only a means to explain the straight line, but a possibility of a quantitative measure of acceleration and condensation as well. If the displacement downwards, recognized as acceleration, occurs at a pace that is determined by the value of the derivative $a = dt_o/dt_p$ of Equation (2), the linearity of the straight line will be preserved over time. Differentiation of Equation (2) yields

$$a = -C_2 t_o / t_p \quad (3)$$

The quantity a thus denotes the acceleration of each trait appearing at the ontogenetic age t_o .

Such a regular displacement of developmental traits is the result of an appropriate shortening of all preceding stages, a shortening recognized as condensation. The quantity of condensation, denoted q , is the relative difference of two values of acceleration at adjacent points on the lines. This difference is the derivative of acceleration with respect to t_o . Hence $q = da/dt_o$, and differentiation of Equation (3) yields

$$q = -(C_2 + 1)/t_p \quad (4)$$

This analysis shows that the straight line in the diagram is coupled to a continuous and regular shortening of developmental stages, i.e., condensation. The formula implies a systematic decrease of condensation over time, which is intuitively sensible since the more a stage is shortened, the more difficult it must be to shorten it still more. However, I find it remarkable that condensation obeys such a simple formula, depending as it does on one variable exclusively – the age of the trait.

Maybe, though, that the simple regularity of condensation, and hence of the presence of the straight line, isn't so remarkable after all, because, as we found in a previous section, condensation is a consequence of a selection process that is independent of the irregular external contingencies.

As we can see, the formula implies the possibility of a quantitative assessment of condensation and a couple of examples may clarify the significance of the formula. Since the traits of the human embryo emerged very early on the evolutionary time scale, in fact several hundred million years ago, the condensation of these traits is quite small, actually of the order of 3% over 10 million years. As a second example, we may choose the acquisition of oral language of a modern child, which, according to the model, is condensed 3% per millennium. Such small values are of no practical significance. The values of condensation of traits

appearing at higher age are bigger. Thus, for a modern child, the acquisition of Newtonian science is found to be 5% per decade. In the present work, though, there is no need to use these specific values of condensation, because the suggested model of evolution is merely outlined in a most general form.

It may seem, though, that condensation has little influence on evolution at large. I can imagine a process of evolution without condensation, proceeding in much the same way that it actually has gone through. Generation times would just be longer. However, one must assume a random variation of generation times. Then, as discussed in the above section of population biology, a population with somewhat shorter generation time would reproduce more effectively and win the competition with populations with longer generation times. This is how natural selection works, in this case actually in a form that is independent of external conditions. I thus conclude that condensation is an inseparable part of the evolutionary process.

Condensation and Terminal Addition

It is important to clear out the how of the counteracting processes of condensation and terminal addition are working. I therefore try to make it easy to grasp with a highly idealized illustration, intended to facilitate the understanding of the concepts. At the top these columns, sexual maturation sets in, marking the end of ontogeny. The figure illustrates condensation of early appearing organs during the course of evolution. Due to condensation of preceding organs, subsequent organs are displaced towards earlier appearance, a process recognized as acceleration.

Figure 3. The vertical columns illustrate four life histories at different points of time in the evolutionary history of a species at occasions when terminal additions have occurred. The blocks in the columns represent developmental traits. We may think block C as representing a primitive back-bone, block D a primitive heart, E the lungs, and F the modern heart. It may also be suggested that the blocks represent stages in the human cultural evolution. Thus block C may represent oral language, D written language, E arithmetic and F algebra. Between these columns one may think of a lot of intermediate life histories in which there has been a continuous condensation and shortening of generation length. The curved lines illustrate acceleration and the distance between them at each point of time corresponds to condensation.

The figure also illustrates how new organs are added at the end of ontogeny, a process identified as terminal addition. As we can see in this picture, the lengthening of generation time and the often-accompanying growth of body size, being normal trends in the great perspective of evolution, don't contradict the conclusion of a simultaneous presence of condensation. Such a lengthening might however be somewhat reduced by condensation. In this way, maturation

time escapes from becoming awkwardly long, but this conclusion is a consequence, not a cause, of condensation. The fact that condensation and terminal addition give a superimposed result is probably responsible for the fact that the occurrence of condensation has not been given appropriate attention in prevailing discussions of evolutionary processes.

Terminal additions (including increasing body sizes) must in most cases have been more advantageous than the disadvantages due to the consequential prolongation of generation time, because otherwise the new traits could never have come about. This means in these situations that ordinary environment-dependent natural selection in the formation of new traits is stronger than the accompanying selection for shortening of generation time. Nonetheless, it seems reasonable to assume that, during the process of evolution, the counteracting processes of condensation and terminal additions have been in action simultaneously and independently of one other.

The sequence of stages at the top of the columns illustrates what is normally considered as the evolutionary history of the species. Of course, it is unavoidable to observe that this sequence of traits is observed in the sequence of traits building each individual's life history as well. This is recognized as the contentious concept of recapitulation that I have mentioned above.

An Explication of the Regular Temporal Structure of Evolution

The straight line in Figure 2 indicates a large structure of evolution that insists on explanation. In Figure 3, the four columns illustrate in an idealized way four individual developmental courses at the occasions of terminal additions. Such major transitions are certainly occurring at highly different time intervals because they are molded by natural selection and thus dependent of the haphazardly varying external conditions. Between these occurrences one may envisage a great number of individual developmental courses (not illustrated in the diagram), incessantly exposed to selection pressure for condensation. In my analysis of population biology, I found condensation to be independent of external contingencies. Therefore it seems possible, maybe even plausible, that it could exhibit some degree of regularity. If so, the lines of acceleration in Figure 3, i.e., the lines connecting the onsets of developmental traits would be even as indicated in the figure. As a consequence, the irregular time intervals at which terminal additions have occurred in the course of evolution would be preserved as corresponding time intervals at which traits are added in subsequent individual developmental courses. This structural similarity could then be illustrated as a straight line as that in Figure 2. Since this line, formed on the basis of empirical data, in fact is found to be straight, the assumption of the regularity of condensation is confirmed. One may thus conclude that in spite of highly irregular conditions, the evolutionary process has nevertheless, under the influence of the environment-independent functioning of condensation, accomplished a large-scale regularity in its outcome as manifested as a straight line in Figure 2.

A different way to arrive at this conclusion is to assume that if condensation hadn't been independent of the environment, it would probably not have been regular and if so, the temporal structure of the evolutionary process wouldn't have been preserved in the developmental process. Then the line wouldn't have been straight.

Let us, in order to make this reasoning easier to follow, consider an example related to the features of the diagram of Figure 2. In this diagram we can observe that the temporal gap

between the evolutionary occurrences of the primitive heart and the four-chamber heart is much smaller than that between, say, the appearance of cortical neurons and oral language. The same difference is observed in the timing of these traits in the individual growth process as seen on the vertical axis. This demonstrates that the temporal structure of the evolutionary process is preserved in the developmental process, thus giving additional support to the above reasoning. Of course, one should not forget that the mathematical analysis of the straight line has shown that the regularity of condensation is a consequence of the linearity of the line, but the task of the reasoning has actually been to explain the feature of the line of being straight.

The main conclusion is that, *in spite of the irregular time intervals at which changes have occurred in the course of evolution, there is a large-scale regular structure of these changes, revealed when also the developmental process is taken into account.*

This regular structure is a result of a process being coupled to a form of natural selection that is independent of the external environment.

Empirical Support

An important question is of course if the discussed selection pressure for condensation in fact has been exerted in evolutionary lineages of living creatures and if so, if such a process can empirically be studied. A fundamental difficulty hampering this question is that the embryonic development of ancestral organisms is not available for studies and therefore that longitudinal study of condensation in a lineage cannot be performed.

This difficulty restrains all attempts of examinations of temporal displacements as studied in the field of heterochrony. For the present analysis, studies of the age of an embryo are the most urgent. However, as Balinsky (1975 p. 302) points out, the age of an embryo is often not known, and in animals other than mammals, the rate of development is dependent on the temperature of the environment making an assessment of the age of the embryo especially uncertain. Moreover, the size of the embryo is no true indicator of its degree of development, as the dimensions of the embryo vary to a great extent. As to the morphological peculiarities of the embryo, there are certain limitations even to this approach. Finally, as he indicates, the development of different parts or organs of the embryo is not always strictly coordinated in time. In this situation, I think, we are restricted to look at the largest patterns of the evolutionary process. Thus, from textbooks on embryology like the one by Balinsky, we may contend that in present-day vertebrates, the most vital somatic organs (the heart, the kidneys, and the like) are moulded very early in the gestation period.

One must remember in this context that new traits in their first emergence appear as terminal additions because, as is generally assumed, novel traits appearing early in the embryogenesis are most probably affecting subsequent forms in a deleterious way.

Then, after this occurrence, condensation of this and preceding traits are causing the observed early appearance of basic embryonic and juvenile traits.

Since, as we have seen, developmental traits are found to have a regular temporal dependence of the intervals at which evolutionary events have occurred, it would be interesting to find out if the very process of evolution would display some degree of regularity as well. In order to find such regularity, one needs some sort of measure of evolution itself. This leads us to the second way of interpretation of the straight line in the diagram of Figure 2 – an interpretation in terms of complexity.

COMPLEXITY

Common Views

In the extensive literature on evolution, many authors seem to be hesitating about how to determine the direction of the evolutionary process; about how to characterize, as they say, the arrow of time. A common though intuitive notion is that the direction can be characterized as a steady increase of complexity.

In the present work I maintain that the concept of complexity provides a promising way to get a deeper understanding of the very process of evolution. A recent contribution to the literature on complexity in connection to evolution is given by Lineweaver et al. (2013), having collected contributions from several researchers in the field.

A common problem, expressed by many of these authors, is the lack of a definition of complexity. But, as the editors ask, even without a definition or a way to measure it, isn't it qualitatively obvious that biological complexity has increased? Do we really need to wait for a precise definition to think about complexity and its limits? (*ibid.* p. 5). I find this remark highly relevant for my present analysis.

Melanie Mitchel (2009 pp. 96-111) describes many forms of complexity in specific fields such as complexity of size, entropy, information, thermodynamic depth, fractals, and degree of hierarchy. She contends that complexity is discussed in several fields of research such as in genetics, in Evo-Devo, and in studies of chaos.

As the history of science shows, the comprehension of a new concept often starts with its measurement. This practice can be seen as exemplified by Newton's measurement of force and Joule's measurement of energy. Actually, there are some fundamental concepts that cannot be defined by reference to still more fundamental concepts. I think that complexity may be such a concept. If so, it is futile to wait for a definition and instead it seems better to develop methods of its measurement and explore the explanatory consequences of such a measurement. I have in a previous publication (Ekstig 2010 A) suggested such a method that shortly will be presented in the next section.

Even if one cannot formulate a stringent definition, there is need of a description in ordinary terms of what complexity means. As an attempt at such a description, I would here like to use a simple formulation by McShea and Brandon (2010), implying that complexity means the number of parts or the amount of differentiation among parts within an individual.

Most authors express the intuitive notion that complexity has been increasing during the course of evolution. Since natural selection is generally seen as furnishing the prime mechanism of evolution, it is more or less tacitly assumed that increasing complexity has come about by the action of natural selection.

But there are also attempts to explain increasing complexity even without the action of natural selection (McShea and Brandon 2010, Kauffman 1993, 2013). An objection against these attempts is raised by Lineweaver (2013 p. 7), maintaining that a definition of complexity without the involvement of natural selection merely describes an increase in entropy. However, many authors resolutely deny the possibility of a meaningful use of the concept of complexity in the context of evolution altogether, referring as they do, to the lack of a stringent definition. It seems in this context that Robert Trivers's opinion has had a pervasive influence through his statement: "There exists no objective basis on which to elevate one species above another.

Chimp and human, lizard and fungus, we have all evolved over some three billion years by the process known as natural selection” (Trivers 1976). In a certain meaning, all species can of course be said to be emanating from the very first forms of living organisms, since all have parts of their DNA conserved from these old organisms. I think that that is what Richard Dawkins has in mind when stating that all lineages have had exactly equal time to evolve since the dawn of life and he ardently discards the idea that animals could be ranked on a “higher or lower” scale (Dawkins 1992 p. 263). He is somewhat more open, though, to the concept of progress, especially as a result of arms race (Dawkins 2004 A pp. 496-497).

However, Dawkins doesn’t think that anybody would deny that there has been a broad overall trend towards increased information content during the course of human evolution from our remote bacterial ancestors (Dawkins 2004 B p. 101) and then, in the same context, he refers to another scientist in suggesting that information content of a biological system is another name for its complexity (ibid p. 102), a contention that, at least, he doesn’t deny. It seems to me that Dawkins here comes quite near the notion of complexity as a quantity that is increasing in evolution.

I think that Trivers’s and Dawkins’s opinions in this matter can be understood insofar as when expressing a notion of a change of an entity, one has to rely on some kind of quantitative assessment, a measure that, as commonly observed, is lacking in the case of complexity. Yet despite this problem, there is a widespread opinion, even as we have seen amongst scientists, to hold on to the view of a generally increasing complexity in the evolutionary process, a view that is maintained with or without the involvement of natural selection.

In the present work, I strongly adhere to the view, expressed by so many scientists, that complexity has successively been increasing during the evolutionary process and that this process mainly is a result of natural selection. However, the view that increasing complexity is driven by natural selection requires a more detailed analysis that I will come back to. But, first of all, can complexity really be measured?

The Assessment of Complexity

As a point of departure, I make the assumption that there is such a concept as complexity that has been continually increasing during the course of evolution. The intuitive view of such a process relies on how evolutionary key novelties have been appearing over time. Such an indication is discussed by Carl Sagan in the form of a picture he calls *The Cosmic Calendar*. In this picture he presents evolutionary key novelties, including some cultural events as well, between which there are successively shorter time intervals (Sagan 1978 pp. 14-16).

In his comprehensive overview of organic evolution, Richard Dawkins (2004 A) demonstrates the same pattern and Yuval Noah Harari (2012 p. viii) provides in the same vein a timetable of biological and cultural history.

As we can see from these accounts, the novelties appear irregularly but at rapidly shortened time intervals thus harmonizing roughly with the logarithmic time scale of Figure 2. One may raise the objection that the choice of these key novelties is subjective, but it seems to me that the choices, though intuitive, are reasonable and probable shared by many people. It must be emphasized, however, that these accounts of evolution cannot be used for an assessment of the rate of evolution because to that end one also needs an estimation of the degree of change or quality of each novelty. I suggest that the concept of complexity can be used for that purpose.

I have in my construction of the diagram of diagram of Figure 2 suggested the line in the diagram to be a representation of complexity (Ekstig 2010 A). The justification of this conjecture is relying on the explanatory possibilities it may infer. I developed a numerical analysis making possible an estimation of the increasing values of complexity during the evolutionary process, a procedure that can be seen as an operational definition of complexity. I suggest this particular form of complexity to be called *evolutionary complexity*.

The interpretation of the straight line in Figure 2 as illustrating evolutionary complexity relies on two assumptions. The first is that it has been incessantly increasing during the course of evolution. This assumption is supported by the fact that many scientists agree with it as I have pointed out above. Therefore, I don't find this assumption controversial.

The second assumption is that evolutionary complexity increases during the developmental process as well. The problem with this assumption is that all information about the growth of an individual creature is present in its genome at the very beginning of the developmental process and doesn't thereafter change (with some sporadic exceptions) and therefore one could say that the information for the developmental process has been present all the time from its beginning. I think, though, that it is important to distinguish two features of the DNA. First, it contains information about how to build a body and, second, it performs the building work as well. To use a metaphor – the DNA is both the architect and the builder's workman.

As we know, the architect's plan is available from the beginning and is step-by-step accomplished by the builders. In a similar way, the building of an animal body is accomplished, at the supervision of the genes, by means of successive additions of new parts and more connections between the parts, which means an increase of complexity according to the definition of complexity that I suggested above. Therefore I conclude that evolutionary complexity is increasing during the developmental growth of an individual animal. The same reasoning can be applied to the development of our intellectual faculties, though in this case, the information and instructions are stored in the social environment.

To begin with at the formation of the procedure of measuring evolutionary complexity (Ekstig 2010 A). I made the assumption that its growth may be following an exponential function. Therefore, I assumed as a starting hypothesis that evolutionary complexity is following increasing values similar to the negative tail of an exponential function. Hence, its growth is assigned values between 0 and 1.

The next step is to construct a diagram of complexity on a linear time scale. To this end, one must take into account that the position of each point on the line in the diagram of Figure 2 is determined by two time coordinates, one for evolution and one for development.

These two time coordinates for each trait is now represented by a number of pairs of points with their time coordinates on the common linear time axis stretching backwards from the present point of time, thus forming two separate sequences. Next, these pairs of points should be distributed in the diagram according to their coordinates of complexity, up to now undetermined, which is a most crucial procedure.

To that end, one must keep in mind that every pair of these points originates from one and the same point on the line in the diagram of Figure 2, thus representing the same value of complexity. The coordinates of complexity of these points are determined by a tentative formation of an evolutionary curve that gives the most sensible shape of the developmental curve. Because the time axis of the diagram is linear, it is impossible, due to the great difference of temporal extension of the processes, to display the two curves in one and the same diagram. Nonetheless, the procedure can be executed in a numerical mode.

The result of this adjustment of the two curves to each other indicates that an exponential form of the evolutionary curve is unable to give a sensible form of the development curve. Rather, I found that complexity during the course of animal evolution is best described by means of a sequence of exponential functions with increasing bases.

This means that complexity has increased in a superexponential pace, thus growing in an extremely slow pace in early evolutionary times and much faster in the cultural realm (Ekstig 2012) (A superexponential function is a variant of an exponential function in which the base is continuously increasing). The resulting diagram from this procedure is reproduced in Figure 4 in which only the last 100 years of the evolutionary curve is shown.

I suggest that we consider this assessment as a hypothesis and examine its explanatory possibilities. As I already have pointed out, the understanding of evolution has been strongly hampered by the lack of a method for its measurement and I maintain that the suggested method for the measurement of evolutionary complexity gives a possibility to discuss the progress and direction of evolution.

The numerical analysis indicates that evolutionary complexity has been steadily increasing during the course of evolution, although the increase isn't following a simple mathematical formula. A table of its values as obtained from the suggested procedure is given in Table 1.

In the present work, though, I think there is no need of using the specific values of evolutionary complexity as received by the measurement. The measurement has its justification insofar as it makes statements about increasing complexity better grounded. Furthermore, it makes possible the construction a diagram of complexity versus time for the evolutionary process at large, without the requirement of specifying the precise values on the axes. As it turns out, such a diagram implies an entry for several basic insights into the evolutionary process being presented and analyzed in later sections.

Figure 4. A combined diagram over development (squares) and evolution (diamonds) on a linear time scale. The curves are adjusted to each other to give the most sensible shape of the development curve. The evolutionary curve has its onset 600 million years ago which is a point on the linear temporal axis of this diagram, positioned 600 km to the left. At the point of time 20 years ago, the curves coincide, which corresponds to the point called The critical point in the diagram in Figure 2. The diagram is reproduced from (Ekstig 2010 A).

Table 1. Some relative values of evolutionary complexity as given by the numerical program as reproduced from Ekstig (2010 A)

Evolutionary time (years ago)	Individual age (years from conception)	Relative value of evolutionary complexity
600 million	0.06	10^{-26}
6 million	0.38	0.16
1 million	0.76 (birth)	0.30
25,000	3.2	0.52
1,200	10	0.80
400	16	0.92
100	28	0.98
20	52	0.99

It is interesting to note that the evolutionary process can best be explained by means of a time scale running backwards, starting from the present point of time. Such a feature contrasts sharply to the ordinary way of studying processes in nature by following the direction of time itself, and I think it reflects the fact – by no means unnoticed – that the features of living organisms are best understood on behalf of their bygone history. This result also concurs with the fact that future routes of evolution cannot be predicted. However, the nearest future can in a limited meaning be seen as determined by natural selection. As Dawkins (2004 B p. 103) points out, natural selection is by definition a process whereby information is fed into the gene pool of the next generation. This, as I see it, explains the continuity of the evolutionary process.

Accelerating Evolution

There is a common notion that evolution is an accelerating process. According to the suggested procedure of measuring evolutionary complexity, I determined the successively increasing bases of the consecutive exponential functions representing evolutionary complexity. From these bases one can derive the doubling times of the complete process.

This procedure is described and the resulting doubling times at different evolutionary epochs are given in Ekstig (2012). Here, I reproduce in Figure 5 the obtained graph of the doubling times which gives a conspicuous picture of a significant feature of evolution. Added to my own values are a couple of other measurements for the latest period of time.

If evolution were following an exponential course because of its cumulative character, the doubling time would be constant. However, the present result indicates the overall trend to be much more rapidly increasing with rapidly decreasing doubling times, implying a superexponential evolutionary course. The result implies that at about 100 million years ago the doubling time was about seven million years. Then during the following period of animal evolution it decreased to 600,000 years. At the onset of human evolution the doubling time was about 200,000 years to successively decrease to about 3,500 years at about 400 years ago, a value being characteristic for the pre-Galilean scientific evolution.

For the most recent 200 years, human scientific activity shows a dramatic progress with a doubling time of only 20 years. Finally, information technology over the last century follows a still more rapid rate with a doubling times quickly decreasing to the present value of only 18

months. The diagram shows that evolution at large is following an accelerating pace that in the present time has reached a tremendous rate. Ray Kurzweil (2005) has discussed this trend, suggesting that evolution soon will reach an unlimited speed, thus arriving at what he calls the singularity; a really alarming prospect. If evolution had been found to follow a hyperbolic function, one could expect it to end in such a singularity.

Figure 5. The doubling time of complexity versus evolutionary time. Squares represent animal evolution, diamonds hominid and human evolution including, for the last three points, pre-Galilean scientific evolution, triangles post-Galilean scientific evolution adapted from Jinha (2010), and circles the evolution of information technology adapted from Nagy (2010). The diagram is reproduced from (Ekstig 2012).

However, I have built the analysis of increasing complexity on a sequence of exponential functions that, although rendering the complexity a rapidly increasing pace, doesn't necessarily end up in such a precarious singularity.

The concept of evolutionary complexity has hitherto in this work been discussed in descriptive terms. I now suggest an explication of its growth.

A Self-Reinforcing Feedback Process

An intrinsic feature of life is that living organisms apply the remarkable principle of starting, so to say, from scratch in the formation of each new generation. Only the genetic information is preserved, thus allowing the growing individuals to take advantage of the experiences collected by parents and previous generations. This information is then sieved by the external environment before it is fed back to the next generation or, as I have discussed above, even sieved by a selection process without the involvement of the external environment. In short, this is natural selection combined with a feedback process.

The concept of positive feedback is a source of growth of a system. It originates from the technology of electronic amplifiers, in which part of the output voltage is coupled to the input side. In this way the voltage, which I here call the substrate, is amplified by a feedback loop, a mechanism that can give a rapid and nearly unlimited degree of voltage amplification. This

principle can be transferred to many kinds of processes. Of special interest in the present context is its application to the evolutionary process. Bernard Crespi (2004) points out that positive feedback can be instrumental in driving many of the most important and spectacular processes in evolutionary ecology. He emphasizes that the self-reinforcing dynamics of a positive feedback generates the conditions for changes that might otherwise be difficult or impossible for selection or other mechanisms to achieve and that it can generate large-scale changes in genetic systems.

Crespi mentions the peacock's tail, the human brain, the extinction of passenger pigeons and the infestation of our genomes by repetitive elements as examples of the many remarkable phenomena in evolution and ecology for the growth of which he suggests the mechanism of positive feedback. To his broad account of cases of positive feedback, I would like to add the implementation of complexity, which I suggest can be seen as a common concept behind Crespi's examples.

According to a common description of complexity it means the number of parts or the amount of differentiation among parts within individuals as I have discussed above. Therefore, the addition of a new trait contributes to the complexity of the species. One may assume that this increase of complexity opens still more opportunities for the species to adapt to the environmental peculiarities and thus to add still more traits. In this way, a species is increasing its complexity according to the principle: the higher its level of complexity, the higher the number of opportunities to add still more traits and thus to increase complexity still more.

Such a procedure, even if the implication of its repetition in the developmental course is taken into account, implies a cumulative process that normally leads to an exponential increase.

Let us consider a typical example of a situation in which natural selection gives rise to a cumulative process. An animal's fur is a shelter against cold climate – the colder the climate, the thicker the fur. Thus, the climate stimulates the fur to grow cumulatively but the fur has no influence on the climate. In order that a feedback process should be applicable, there should be a coupling back from the thickened fur to the climate thus leading to a runaway process typical of a feedback in action. In this case there is no such coupling. In many cases in organic evolution natural selection works that way. Are there cases in which natural selection could give rise to a feedback process?

Let us consider such an example. *Arms race* between predators and prey implies that an improvement of the capability of one side will have influence on that of the other thus leading to runaway improvements of the capabilities of both sides. As Dawkins (2004 A p. 496) points out, arms races are deeply and inescapably progressive in a way that, for example, evolutionary accommodation to weather is not. Therefore, the mutual coupling occurring in arms race comprises, I think, the hallmark of a self-reinforcing feedback process. The improvements of the capabilities involved in this process certainly entails an increase of complexity of both sides leading to the conclusion that the self-reinforcing feedback process in arms race causes a rapid increase of complexity that may be much faster than if generated by a cumulative process only.

Sexual selection is another example of a self-reinforcing feedback process. A typical example is found in the conspicuous ornamental plumage of the peacock's tail. In this case the plumage evolution in the male is coupled to a sexual preference for such a plumage in the female. This means that an improvement of a feature on one side will have influence on that of the other. An important feature of this process, as discussed at length by Dawkins (1988 p. 203), is that the genes for male qualities, and the genes for making females prefer those qualities are evolving together leading to mutual runaway improvements, typical of a feedback process.

Another application of a self-reinforcing feedback process is found in cultural evolution in which the evolution of language is especially elucidating. This case will be discussed in a forthcoming section on cultural evolution.

Of course, such a rapidly growing process as that accomplished by the self-reinforcing feedback process cannot go on unlimitedly. The peacock's tail cannot grow infinitely. It seems that the benefit of the new trait starting the feedback process sooner or later is exhausted leading to the kind of natural selection called stabilizing selection; a situation that may go on until interrupted by the emergence of another new trait that may start a new feedback process.

It is conceded that feedback will give rise to an exponential amplification. The cases just discussed are examples of feedback amplification of complexity thus being expected to increase exponentially with time. Such an exponential increase is determined by the base of the exponential function making possible a nearly unlimited degree of amplification. However, during the extended course of organic and cultural evolution several such amplifications have occurred consecutively, each of which supposedly provided with its own characteristic base that in each case may result in a high increase of complexity over short time intervals. In this way, evolution may be characterized by a stepwise growth of complexity, a feature that will be discussed in a forthcoming section.

In addition to this process, natural selection contributes to a successive cumulative addition of new traits in the evolutionary process that may lead to a large-scale exponential increase of complexity. When also the contributions to the growth of complexity from the feedback instances are added, one may find a large-scale increase of complexity that by far exceeds a merely exponential growth.

Despite the periods of stabilizing selection, when seen in the large-scale perspective of evolution, the total pattern of increasing complexity may very well explain the observed increase of complexity as I have previously found and illustrated in Figure 5.

In this way it seems to me that feedback is an inherent principle of evolution that, together with natural selection, accomplishes the generally large-scale pattern of increasing complexity in evolution – a pattern that natural selection by itself is incapable to accomplish. It is now time to discuss complexity a bit closer.

COMPLEXITY AND THE TREE OF LIFE

Some Authors' Views of Evolution

Many renowned authors discuss the general trend of evolution. Thus John Maynard Smith, together with his co-author, Eörs Szathmáry, contend that living organisms are highly complex and that increases of complexity have depended on a small number of major transitions (Maynard Smith and Szathmáry 1995 p. 3). Such notions indicate a stepwise increase of complexity. Edward O. Wilson, though without using the concept of complexity, expresses a comprehensive view of how life has evolved:

Species emerge quickly and fully formed after a rapid burst of evolution, then persist almost unchanged for millions of years. And, conversely, rapid evolution is driven mostly or entirely during species formation. ...The models of population genetics, the foundation of quantitative theory, predict that evolution by natural selection can be so rapid as to seem nearly

instantaneous in geological time. The models also allow for stasis, or long periods with little or no evolution of a kind detectable in fossils (Wilson 1992 pp. 80, 81).

Somewhat later on he contends:

All contemporary dynastic successions taken together present a complex and strikingly beautiful pattern across the surface of the earth. Now the comparison is to a palimpsest, an ancient parchment on which the current dominant groups are boldly spread and past rulers survive as faded traces in spaces between the lines, in shrunken niches. Mammals, the dominant large vertebrates on the land today, are accompanied by turtles and crocodilians, among the last survivors of yesteryear's ruling reptiles. Forests of flowering plants shelter scattered ferns and cycads, remnants of the prevailing vegetation of the Age of Reptiles (*ibid.* p. 86).

It is interesting to note that Dawkins in his analysis of evolution uses the same metaphor of a palimpsest (Dawkins 2004 A p. 23). This metaphor is concurrent with the present view of evolution inasmuch as new species are added while the previously existing species continue their way of living unaffected.

These instances of thoughts by these three renowned scientists have important bearings on the present analysis. Thus Maynard Smith and Szathmáry's views imply evolution to have proceeded in a stepwise way.

Likewise Wilson argues that there have been stepwise bursts of evolutionary changes between which there have been long periods with little change. I interpret Wilson's view in such a way that evolution is proceeding cumulatively while most species continue to live in the mostly unchanged niches to which they are adapted. Because Maynard Smith as well as Wilson base their statements on initiated observations, I take their words as a basic empirical support for my interpretation.

I think that these rationales can be understood in a more comprehensive way by the application of the concept of complexity and the most direct way to do so is by means of a principal diagram over complexity versus time. From now on in this work, instead of using the concept of evolutionary complexity, I use the generalized concept of complexity.

Complexity and a New View of the Evolutionary Process

I suggest that we start by illustrating the evolutionary process by means of a highly idealized diagram of complexity versus time as shown in Figure 6.

I have previously developed the diagram of Figure 6 as a result of an analysis of the evolution of individual developmental courses (Ekstig 2010 B). In Ekstig (2015) I have given a complementary analysis of the diagram as seen as a result of different forms of natural selection. In the present work I extend this analysis and suggest an explanation of the stepwise increase of complexity as a result of a joint action of natural selection and a self-reinforcing feedback process as we have discussed in the previous section.

It is common knowledge (see for instance Reece et al. 2011, p. 527) that natural selection works in three modes – disruptive selection, stabilizing selection, and directional selection. I have analyzed increasing complexity in terms of these concepts (Ekstig 2015), and in the present work I deepen this analysis.

In Figure 3 the uppermost blocks in each column illustrate the addition of new traits to the individual's developmental course. In this process, the new trait must have some advantage of its establishment in comparison to the already existing traits, and I think such an advantage involves an addition of complexity.

This process is in Figure 6 depicted by the steps in the uppermost line, formed by the self-reinforcing feedback process giving rise to a rapid rise of complexity in evolution, a process that is associated to the traditional concept of disruptive selection.

In the diagram of Figure 6, the stepwise raising curve thus represents species emerging in the complexity space after great though rare bursts of evolutionary transitions. After such a transition, the new species normally stabilizes at a new level of complexity, thus forming a new horizontal line above those previously formed. In this way, the diagram illustrates Wilson's comparison with a palimpsest, a metaphor for the cumulative emergence of new species above former ones.

Furthermore, previously formed species are stagnant, illustrated as horizontal lines, persist to exist in what Wilson expresses as shrunken niches – an indication of the hard competition for room in the complexity space. In order to clarify the steps in the uppermost line in the diagram, I suggest as major transitions in the biological part of evolution the emergence of multi-cellular organisms, vertebrates, terrestrial animals, mammals, and man. Other similar or less prominent transitions may be envisaged in between. After these occurrences, human cultural evolution sets in, the steps of which is discussed later on.

Figure 6. A view of evolution as formed by the processes suggested in the present analysis. The lines represent the complexity of animal species in a highly idealized way although the lines can be interpreted as representing the species per se as well. In this second interpretation, the diagram can be seen as a Tree of Life. The horizontal lines represent stagnant species and the stepwise curve represents the emergence of novel species at the highest degree of complexity. This stepwise curve at the same time represents the common descent of all species. The diagram was first published in (Ekstig 2010 B).

This procedure, when repeated over and over again, leads to a cumulative formation of new species at successive higher levels of complexity. I have suggested this rapid increase to be explained by natural selection and a self-reinforcing feedback process. However, the form of the stepwise curve in Figure 6 isn't just depending on the time interval between the steps but on the height of each step as well, a feature that can be seen as a measure of the quality of the elevation of complexity at that occasion. An analysis of this feature remains to be made. In this

work, I don't specify the details of the curves in Figure 6. It is in the present work sufficient to say that the stepwise curve is a principal illustration of the structure of complexity growth accomplished by the joined effects of natural selection and a self-reinforcing feedback process.

It must be emphasized that the diagram of Figure 6 is highly simplified. Thus, the vast number of species is represented by few lines only. From one such line one may imagine that a lot of related species have emerged, just with slightly diverging features on slightly different levels of complexity. In this way, the complexity space is more or less tightly filled. In the diagram these new species would form horizontal lines lying quite near those of their parent species, although such lines are not shown in the diagram. In this way one may expect that the complexity space will be tightly filled with species.

Such a situation is discussed by Conway Morris (2013 pp. 150-156), concluding that any room for exploring complexity much further is now highly restricted.

Stabilizing selection and directional selection are associated to the cases in which species are kept unchanged or with only small successive changes for long periods of time. Directional selection implies a successive change in a certain direction, for instance towards increased body size, which is a common trend in many species. Such an increased body size keeps most traits unchanged with regard to their function and implies, I think, only a slow increase of complexity. Therefore, the complexity of species applying stabilizing selection or directional selection is represented by the horizontal lines in the diagram in Figure 6.

I summarize this section by pointing out that the rare emergences of radically new species are occurring cumulatively on the uppermost level of complexity, thus rendering the direction of the evolutionary process a significant meaning.

Competition for Room in the Complexity Space

For each of the tightly placed species forming horizontal in the diagram of Figure 6, it may be hard to change to another position in the complexity space because all nearby positions are already occupied. This contention is actually clearly expressed already by Charles Darwin in saying that "competition will generally be most severe between those forms which are most nearly related to each other" (Darwin 1859 p. 121). Daniel Dennett (1995 p. 89) has expressed a similar view, in stating that the odds are heavily against any mutation being more viable than the theme on which it is a variation. What is new in the present view is that competition is seen as occurring in the complexity space.

However, competition of this kind is not present *for species at the highest level of complexity at each point of time, because for them there are no species on higher levels causing competition*. This explains an important feature of this form of the Tree of Life implying that elevations to radically higher levels of complexity occur merely for species dwelling already at the highest level of complexity. Moreover, it gives an explanation of the direction of the evolutionary process, since these elevations to higher levels of complexity occur cumulatively. In this way, evolution becomes asymmetric – it moves mainly in one direction only, the direction of increasing complexity.

This observation is mentioned by Blum (1968 p.175) in his statement that the whole picture of evolution is one in which derivation of new patterns come from modifications of those existing – never by return to a former starting place for a new "try," unless in some very minor instances which we may neglect in our overall view.

Such an instance, though, is accomplished by parasites. These creatures are considered to be evolving towards lower levels of complexity, in the diagram diverging from a horizontal line downwards. However, they are diverging from a species that previously has raised itself to a certain higher level, and therefore parasites don't form a primary type of living organism. Hence they don't, I think, disturb the general conclusions developed in the present work. But maybe parasitism doesn't necessarily lead to a decrease of complexity. As Conway Morris (2013 p. 150) suggests, the interlocking of the genomes of hosts and parasites seems to point towards an under-appreciated degree of complexity.

The reasoning by reference to competition has a most pregnant implication. It means that the evolutionary process is going on in a continuously cumulative way, implying that old species do not suddenly jump up amongst the species dwelling on a much higher level of complexity. Such a transition would need the simultaneous change of many genetic features, which is highly improbable. This reasoning explains the simplicity of the illustration of evolution in Figure 6. The lines are not randomly pointing in different directions or crossing each other. There are no such things as hopeful monsters.

This feature of evolution is clearly demonstrated by Richard Dawkins in his great survey of biological evolution, *The Ancestors' Tale* (Dawkins 2004 A). Although Dawkins doesn't apply the concept of complexity, I find his illustrations of species evolution having much in common with the present model.

The Tree of Life

In the diagram in Figure 6, the lines represent the levels of complexity of animal species in a highly principal way, although the lines may be interpreted as representing the species per se as well, implying that the diagram can be seen as a Tree of Life. This metaphor, introduced by Darwin even before he disclosed natural selection (Darwin 1837), is now widely spread in discussions of evolution. One may find many forms of the Tree of Life in the literature. It seems that Ernst Haeckel in the nineteenth century got pervasive influence with his widely spread picture of the Tree of Life in the form of an old oak, the multitude of branching of which represents the diversity of species.

The form of the Tree of Life suggested in Figure 6 differs in important ways from the traditional form in that it includes the dimension of complexity, perpendicular to the dimension of time.

Furthermore, common descent is formed by the lineage with the highest level of complexity, a lineage represented by the stepwise curve at the uppermost part of the diagram.

Despite the highly simplified form of the Tree of Life it has, I claim, great explanatory value. It can be seen as a summary of many ideas in the present work. Especially, it explains Lamarck's challenging observation mentioned in the introduction, implying that the oldest species are the most primitive in spite of their long exposition to natural selection. The traditional solution of this conundrum is to exclude the use of the terms primitive and advanced – lower or higher – in analyses of evolution, by the same token refraining from the possibility of talking about the direction of evolution.

As I found in my previous measurement of complexity, it displays an accelerating growth. This growth is what is illustrated as the uppermost line in Figure 6. Furthermore, in the reasoning above, I concluded that the accelerating growth of complexity is caused by a

combination of natural selection and repeated self-reinforcing feedback processes. However, if one refrains from the interpretation of Figure 6 as built on complexity and regards it as an illustration of the evolutionary process per se, then also the conclusions in connection to the concept of complexity may be generalized. Thus we may conclude that, although each step in the uppermost line is a result of the disruptive form of natural selection, this process is insufficient in explaining the large-scale accelerating pace of evolution. Instead, these steps are mainly caused by repeated self-reinforcing feedback processes.

The Appearance of Mankind

The cumulative addition of species with successively higher complexity implies that the latest appearing species at each point of time is the one of the highest degree of complexity. This principle has been in action all the way during organic evolution. At present, this species is the human species. As I already have commented, the vast diversity of animal species fills the complexity space very tightly. However, due to the enigmatic extinction of all hominids, there is a broad empty region in the complexity space between modern man and all other animals. This gap makes it easier to regard the human species as different because the borderline between animals and man needn't being drawn in a continuum. It is thought-provoking to fancy about the situation if the *Australopithecus* species or the Neanderthals were still living – by no means an improbable state of affairs. Then it had been a much greater ethical problem to determine which species could be enslaved or be used as food. In the actual state of things, this problem has vanished in that the human species is distinctly separated from the rest of all animals. Harari (2012) discusses this situation in detail.

The question of whether the human species actually can be seen as the one with the highest evolutionary complexity is a highly contentious issue and many authors seem to avoid to comment it. In his book, *The Ancestors' Tale*, Richard Dawkins starts his journey to our ancestors with a point of departure in the human species and he seems to be very careful of how to justify this choice. Thus his justification of his chosen perspective goes like this:

Instead of treating evolution as aimed towards us, we *choose* modern *Homo sapiens* as our arbitrary, but forgivably preferred, starting point for our reverse chronology. We choose this route, out of all possible routes to the past, because we are curious about our own great grancestors (*italics in the original*) (Dawkins 2004 A p. 13).

I think that Dawkins's choice can be understood by use of the concept of complexity. If, for instance, he had chosen to start with the hippopotamus, his diagrams wouldn't have been so simple. I think that his choice to build his diagrams on the human lineage gives the simplest diagram, but I claim that it is only by means of the inclusion of a measure of evolution, here suggested to be complexity, that his choice is justified. Dawkins's many detailed pictures of the evolution of species are, except for this important difference, quite analogous to my picture in Figure 6.

CULTURAL EVOLUTION

Universal Darwinism

As we have seen, the preceding analyses have been based on the discovery of a regular pattern over the last 600 million years of evolution on our planet. The pattern includes the most recent time as well, thus including human cultural and scientific evolution. Indeed, these parts comprise a great deal of the pattern. Therefore, it is interesting to see in what way the discussed principles of biological evolution are applicable to culture as well.

Ever since Darwin, there have been attempts of extension of his original ideas to the field of cultural evolution. Most of these notions have been built on analogies. A great step was taken by Dawkins (1976) with his introduction of the concept of memes as equivalence to genes. Evolution as based on memes is in this conception considered to work by the same principles as that based on genes. Thus, first there is variation so that not all forms of life are identical; undeniably true for cultural forms. Second, there is a selection that chooses those variants that have the highest ability to be spread in the prevailing environment. Third, there is some kind of heredity mechanism through which features of creatures and cultural forms are transmitted, a heredity that in the realm of culture is upheld by memes.

These conditions are thoroughly discussed by Dawkins (1976 and in many other of his works), by Dennett (1995), and by Susan Blackmore (1999), just to mention a few contributors to the extensive literature on cultural evolution in its connection to evolution.

In the above discussion of organic evolution, I emphasized the importance of self-reinforcing feedback in complexity as a central cause of the large-scale structure of evolution. Such a feedback is observed in the field of cultural evolution as well. Thus Richard Alexander (1989) proposes that social competition between and within human groups has implied a feedback of intelligence constantly producing successively enhanced human intelligence. Needless to say, intelligence is a feature of high complexity contents, implying that this feedback can be seen as working on the substrate of complexity.

We will now examine in what way the present model of evolution, as represented in Figure 6, is a good model for cultural evolution as well.

Steps of Cultural Evolution

Figure 6 illustrates the main features of the steady growth of complexity in organic evolution, characterized by major transitions in species at the highest level of complexity, and by the great diversity of stagnant species. The transitions are illustrated as steps in the graph. We now examine to what extent this model is applicable to cultural evolution.

Zimmer (2002 p. 317) suggests that human evolution is marked by five great transitions, the first of which is the separation from the apes appearing some 5 million years ago, pushing our ancestors out onto the African savannahs. The second was the invention of stone tools about 2,5 million years ago and the third the appearance of hand axes. Some half a million years ago, our ancestors learned to master fire and developed a better ability at making spears and other tools. Finally Zimmer mentions the signs of truly modern minds – paintings on cave walls,

jewellery, weapons, and elaborate burials. All these transitions, I think, are good examples of increasing complexity.

Harari (2012) discusses the reasons of the human success and especially emphasizes the significance of the acquisition of language as a unique transition event of the evolutionary emergence of the human species. In the present context, I think one must consider the acquisition of language as an important step in the growth of complexity, because it certainly assumes a nervous system of high complexity. It laid the ground for the uniqueness of the human species and our conspicuous cultural faculties. I suggest the inclusion of some more recent events in our account of important evolutionary transitions, events that are included in the diagram of Figure 2.

The domestication of plants and animals, first appearing around 11,500 years ago, opened the option of abandoning the hunter-gatherer way of living and instead to live in permanent villages or cities. With this way of living followed the possibility of personal possessions and of differentiated tasks in the community. Of special importance was the invention of written language, first appearing around 5000 years ago, that I claim to be an especially important step in the growth of complexity.

I suggest that the next decisive step forward in this summarized historic review was taken in the ancient Greek society. One may especially connect this society to the rise of the ability of arithmetic and geometry. However, after this period, religious forces kept human thought and culture imprisoned for some 1000 years during the medieval period. By the onset of the Copernican revolution, mankind took the next great leap leading to the scientific era starting in western countries and now thriving in a rapidly accelerating pace nearly all over the world. In this way, cultural evolution follows an analogous pattern as that of species evolution, being depicted by the suggested form of a Tree of Life characterized by a stepwise cumulative increase of complexity and an accelerating rate as seen in the decreasing time intervals between the steps. As to the horizontal lines in the diagram, they are interpreted as the level of complexity in societies that by some reason or another not have participated in the growth of science and technology.

A principal difference between organic and cultural evolution is that as soon as a species is split, no reunion is possible and no exchange of experiences is practiced whereas different cultures carry out far-reaching mutual influences. Such mutual influences certainly contribute in a decisive way to the rapid evolution of human culture.

The phenomenon of culture is of course a much more intricate concept than to be represented by a few simple lines in a diagram. And it is indeed highly controversial to suggest different societies to be related to different levels of complexity. In this context I would like to refer to Jared Diamond (1997). In his attempt to explain Eurasian hegemony throughout history he argues that the gaps in power and technology between human societies do not reflect cultural or racial differences, but rather originate in environmental differences.

I would like to highlight Diamond's rationales in that it is not fundamentally a question of ethnical features that makes a distinction between different societies – these differences are by and large due to accidental environmental conditions, especially, as Diamond emphasizes, due to the advantageous occurrence of plants and animals possible to domesticate. After this crucial step, the differences between different societies have been powerfully amplified by various self-reinforcing feedback loops.

Analogies between Biological and Cultural Evolution

My discovery of the regular relationship between development and evolution includes human cultural traits as an important part. Otherwise, the regularity would never have been disclosed and this is, I think, why biologists never discovered it. The diagram of Figure 2 demonstrates how the cultural part of evolution has been united with organic evolution in an integrated, regular, and continuous pattern. As a matter of fact, if we accept the concept of complexity to be a meaningful measure of evolution, the model indicates that human culture provides about half of the total amount of complexity built up on this planet, as demonstrated in Table 1 – by no means an unreasonable result.

Regarding the interpretation of the Tree of Life as depicted in Figure 6 in the realm of human cultural evolution, it is important to differentiate the construction of the human body from our cultural features. The human species can in this context be regarded as an animal, being depicted by a horizontal line in Figure 6, thus indicating that our somatic features have much in common with animals and are changing only slowly. Our cultural manifestations on the other hand, as seen as expressions of complexity, are growing at an extremely rapid pace as compared with the pace of organic evolution. It should be noted that this reasoning doesn't mean that biological evolution has ceased to be in action. It is just that biological evolution proceeds so slowly as compared to cultural evolution that its effects to a large extent are hidden.

As I have pointed out, the diagram in Figure 6 initially depicts the degree of complexity of species. I also suggested that the lines in the diagram could be interpreted as representing species per se, thus forming a Tree of Life. When it comes to the cultural part of the evolutionary process this interpretation must be modified. I suggest that the lines can only be interpreted as representing the degree of complexity of specific cultural manifestations such as the faculties of verbal language, written language, and scientific advancements. However, I would like to suggest that the interpretation of the diagram shouldn't just be restricted to a descriptive demonstration of analogies but being interpreted as an indication of underlying mechanisms as well, especially the question of the application of natural selection.

Natural Selection in Cultural Evolution

In the study of cultural evolution, one may ask to what extent natural selection is applicable to this process. As to this issue, Sir Karl Popper is known to have sharply pointed out the analogy between scientific progress and genetic evolution. He suggested science may be regarded as a means used by the human species to adapt itself to the environment and asserts a fundamental similarity between the three levels of adaptation: genetic adaptation, behavioural learning, and scientific discovery (Popper 1972).

Within sociobiology, as developed by Edward O. Wilson, many human behavioural and social patterns are considered to be evolved through natural selection. Especially, Wilson concludes that gene-culture coevolution is a special extension of the more general process of evolution by natural selection (Wilson 1998 p. 128). Wilson emphasizes that culture and hence the unique qualities of the human species will make complete sense only when linked in causal explanation to the natural sciences, biology in particular (*ibid.* p. 267). However, I think that the role of natural selection remains to be discussed in more detail.

The Process of Heredity in Cultural Evolution

In his thought-provoking book *The Selfish Gene*, Richard Dawkins (1976) suggests cultural evolution to be analogous to biological evolution, primarily inasmuch as there is a corresponding kind of hereditary principle, the notion of memes, in the field of cultural evolution. Thus for instance, it has been asked if religion in human groups has evolved due to an assumed advantage for survival of the group. This might be an open question, but the main reason, as Dawkins expresses it, for a cultural trait to have evolved in the way that it has, is simply because it is advantageous to itself (ibid. p. 214).

When applying the concept of competition as discussed in the explanation of the diagram of Figure 6, I think one may conclude that competition is a driving force for cultural change as well. Thus Dawkins distinctly expresses such a notion: "If a meme is to dominate the attention of a human brain, it must do so at the expense of 'rival' memes (ibid. p. 211). Daniel Dennett articulates a similar view: "Minds are in limited supply, and each mind has a limited capacity for memes, and hence there is a considerable competition among memes for entry into as many minds as possible" (Dennett 1995 p. 349). It is easy to observe that, for instance, there is an incessant competition between different religions and sects, which means a competition of space in people's brains.

Complexity in Cultural Evolution

Regarding biological evolution, I have suggested the concept of complexity to have high explanatory power. We will now discuss if the concept of complexity is applicable to culture as well and if it has increased with time. Many authors intuitively anticipate the notion of a high degree of complexity in the human cultural evolution. Thus John Tyler Bonner points out that instead of all neurons and their connections being specified in the genome, only certain general parameters are specified. In this fashion, it became possible to produce nervous-system structures far more complex than anything the genes might have specified in detail. These structures are the prerequisites for human abilities in learning, teaching, and communicating (Bonner 1988 p. 192).

As to the increase of complexity, Ray Kurzweil (2005) has emphasized the rapid growth of complexity in human evolution. He regards technological evolution as an extension of organic and cultural evolution. He points out that each paradigm develops through three faces in an S-shaped curve and that evolution, both in its biological and technological expression, evolves through a series of such S-shaped curves forming a soft stair-like curve, a view in precise concordance with the diagram in Figure 6.

The Evolution of Verbal Language

As I already have pointed out, the acquisition of language forms a decisive transition event laying the ground for the emergence of the human species. I think that this event marks the transition from natural selection of the traditional form to memetic selection of the form suggested by Dawkins – both these forms of selection being superimposed during this event to be successively dominated by memetic selection. This is so because this form of selection,

driven by the immaterial units of memes, results in a mode of evolution that is enormously much faster than natural selection working on the inheritance of the material units of genes. Such a great difference of the rate of change is perfectly depicted and understood by means of the logarithmic time scale allowing for a superposition of the two processes.

Susan Blackmore (1999) claims that it is the ability to imitate that makes the human species different. She assumes that people will both preferentially copy and preferentially mate with people with the best memes – especially in the case of the best language (*ibid.* p. 104). This is sexual selection, which, as I have emphasized above, implies a source of strong increase of complexity. Since mating is coupled to genetic evolution whereas imitation is related to a memetic evolution, the first steps of verbal evolution initiated, one could say, the transition from genetic to memetic evolution. It must be pointed out, though, that not all biologists, not to say all linguists, accept the notion of human culture as a product of Darwinian evolution. Especially regarding language, the renowned linguist Noam Chomsky is known to fervently disagree with such an idea. However, Daniel Dennett rejects Chomsky's approach (Dennett 1995 p. 390).

The question in what degree the evolution of language is driven by natural selection is a controversial question, discussed at length for instance by Dennett (1995). It seems plausible that the ability to acquire language is promoted by high intelligence and cleverness, features that certainly had high survival value in the days when all kinds of environmental hazards constantly threatened the survival of the small bands of humans. In such situations, language has certainly been beneficial for survival. But is this process really Darwinian? I think that the survival isn't coupled to a particular physical environment because the causal relation between environment and the acquisition of language isn't as apparent as that for instance between a cold climate and a thick fur. One may say that the verbal ability is equally beneficial in any physical environment. But if the social environment is taken into account, the situation may be quite different, because what is important in the social environment in this context is actually the verbal ability of the population.

Therefore, there is a kind of mutual causal coupling between the individual verbal ability and that of the population. When a child grows up it will contribute to the verbal level of its social environment that enhances the learning of language in the next generation of children. This situation means of a type of self-reinforcing feedback mechanism that I think has had a strong effect on the evolution of language. We may recall that the feedback principle is discussed above in connection with the organic part of evolution.

Thus, in the case of the evolution of language, there is a kind of mutual coupling inasmuch as the child, when grown up, has impact on its environment that has consequence for the next generation of children. This process really involves the hallmark of self-reinforcing feedback: the same causal loop repeating generation after generation. This feedback mechanism, I claim, has had a strong effect on the evolution of language and has caused its rapid changes in comparison to organic changes.

There may be a more general application of the action of feedback in the evolution of the human brain. Thus Daniel Dennett (1991) concedes that "the haven all memes depend on reaching is the human mind, but the human mind is itself an artifact created when memes restructure a human brain in order to make it a better habitat for memes." Then he continues: "The memes enhance each others' opportunities: the meme for education, for instance, is a meme that reinforces the very process of meme-implantation" (*ibid.* p.207). Such mutual

couplings, typical for feedback, have, I think, had a decisive importance for the extremely rapid growth of the human brain as seen in comparison with other somatic traits.

Condensation and Terminal Addition

The increase of verbal ability in a society is coupled to an enhancement of children's verbal skillfulness. Such an enhancement is associated to an earlier acquisition during the child's growth. In the terminology of the present work, we may conclude that there is a condensation of verbal ability. Likewise, as all of us have observed, young people continuously invent new words and a new vocabulary that, in the terminology of the present work, may be seen as terminal additions. Thus I conclude that the concepts of condensation and terminal addition, as developed in the field of organic evolution, are acting in the field of language evolution as well.

Processes in the Evolution of Written Language

The next point after that of verbal language on the line in Figure 2 is written language. I think it is plausible that for instance in the ancient Greek society, writing was an activity exclusively performed by adult persons. I imagine the situation to be the same for the runic writing amongst the Nordic Vikings. But nowadays, most children exercise writing. This has of course to do with intentional education. I think that progress in the western society and the Eurasian hegemony to a large extent must be seen as a result of the organization of universities and, somewhat later, of school systems. During the last 200 years, there has been an awakening political awareness of the importance of education for the wellbeing of the population and that this education must be extended over merely religious indoctrination as essentially was its task in medieval times.

Moreover, education has substantially improved its pedagogical methods resulting in a rapid enhancement of learning. This also means that the children learn the specific technics at successively earlier age; in other words, there is condensation in children's learning.

It may be interesting to see in this context that even the formation of the letters has gone through a process of simplification. The gothic letters from the sixteenth century have successively been developed into more simple forms that certainly have made reading and writing more easily acquired, in this way making earlier learning possible.

In the field of evolution of written language, the changes are intentionally brought into use. This leads as to the application of intentional selection; the primary type of selection in the fields of science and technology.

Processes in Scientific Evolution

As we can see in the diagram of Figure 2, the scientific evolution forms a considerable part of the pattern. It is therefore of interest to see if one can talk about analogies between the biological, cultural and the scientific evolutionary processes as well as similarities in mechanisms. There is a remarkably early formulation of such a notion, expressed by the 1905

Swedish Nobel laureate in chemistry, Svante Arrhenius (1859-1927) in a book from 1907, thus at the time when the discussion of Darwinian evolution was intense.

It is with ideas as with organisms. A lot of seeds are sown, but only a few will grow, and amongst the living things being evolved from them, most are weeded out through the struggle for existence, and only a few will remain living. In a similar way, ideas that are most successfully corresponding to nature are gradually selected (Arrhenius 1907. pp. 175-176, my translation from Swedish).

As we can see, Arrhenius associates the selection of ideas to the Darwinian concept of struggle for existence, in other words, to natural selection. However, there is an important difference in that, in the field of scientific evolution, the selection is intentional.

I would like to mention in passing that Arrhenius is the discoverer of the coupling between atmospheric carbon dioxide and the greenhouse effect; an issue of current interest in our own time.

The school courses in mathematics and physics, as traditionally given in many classrooms, are usually organized so that the sequence of subjects more or less parallels the historical evolution, whether this parallel is made explicit or not. This observation is in concordance with the Jean Piaget's principle of genetic epistemology.

By means of this concept, Piaget suggested that there is a parallelism between the progress made in the logical and rational organization of knowledge found in the history of science and the corresponding formative psychological processes developed in children (Piaget 1970 p. 13). Piaget reported, together with his co-author, an investigation of the relationship between the child's mental development and the cultural and scientific history, restricted to the fields of mathematics and physics. In these fields, the authors observed surprising coincidences in method as well as content and, as they emphasized, very striking common features. What is interesting about this observation is that children construct old concepts without ever being taught about them (Piaget and Garcia 1983 p. 292). Piaget's observation is especially interesting for the present model, because it emphasizes the important role of children in the process of scientific evolution. This, as we may recognize, is in line with the present model, accentuating as it does the importance of the developmental process in evolution. Especially, condensation is such a process.

The evolution of science is connected to the intentional education and the effect of school systems. These occurrences have certainly implied a change towards earlier acquisition, i.e., condensation, of the central concepts of science – indeed significant conditions for the rapid evolution of science.

Moreover, I think that the progress of scientific evolution can be accounted for by a self-reinforcing feedback process, in which the results of scientific research successively are transmitted to school and university curricula, thus enhancing the possibilities of continued progress.

I have illustrated the contribution of science to the superexponential increase of complexity in Figure 5. Of course, one must be aware of the fact that the assessment of complexity is performed by means of different methods in the different fields, and therefore conclusions of the pattern shouldn't be drawn too far. Yet, despite this limitation, the present analysis of scientific progress contributes to the suggested overarching view of evolution as an integrated process of biological, cultural and scientific evolution.

The Human Species – a Unique Species

It is, I claim, the cultural evolutionary process that contributes most to the superior complexity level of mankind. This part of the evolutionary process, according to my assessment of complexity, contributes to as much as half of the total evolutionary complexity developed on our planet. I have discussed this interpretation at length in previous publications (Ekstig 2010 A, 2015). According to the model of evolution proposed in the present work, it is the latest appearing species that takes the position at the highest level of complexity. In our own time, this species is the human species. This gives us reason to place the human species at the highest position in the hierarchy of living creatures. This conclusion concurs with the intuitive though controversial notion of man as the summit of evolution.

In fact, this contentious notion can be traced back to the medieval idea of the Great Chain of Being, indeed even to Aristotle. It is interesting to note that this obsolete idea comprises a hierarchical but not a time dimension, whereas many scientists of today, for instance Dawkins in *The Ancestor's Tale* (Dawkins 2004 A), arrange life on a temporal but not on a hierarchical dimension. The present model, as we have seen, attempts to describe the evolutionary process by the application of both these dimensions.

The notion of mankind as a unique and superior species is a highly controversial issue not frequently expressed in scientific literature. However, a couple of examples may be mentioned. Thus, Carl Sagan eloquently emphasizes our unique intelligence:

We are a thinking species. That's what we are good at. We're not faster than other animals, we're not better camouflaged, we don't dig better, swim better. We think better. And because of our hands we build better. That's our peculiar genius and the chief reason for the success of the human species (Sagan 1989).

Likewise, Daniel Dennett in his broad survey over Darwinism boldly states:

People ache to believe that we humans are vastly different from all other species—and they are right! We are different. We are the only species that has an *extra* medium of design preservation and design communication: culture. That is an overstatement; other species have rudiments of culture as well, and their capacity to transmit information “behaviorally” in addition to genetically is itself an important biological phenomenon, /.../ but these other species have not developed culture to the takeoff point the way our species has (Dennett 1995 p. 338).

Furthermore he points out that cultural evolution operates many orders of magnitude faster than genetic evolution, and this is part of its role in making our species special (ibid p. 339). As we have seen, such a different rate of evolutionary changes is a central component of the present model. In his ambition to strengthen human dignity, American philosopher George Kateb fervently articulates the superiority of mankind amongst all species:

We human beings belong to a species that is what no other species is; it is the highest species on earth—so far. /.../ All other species are more alike than humanity is like any of them; a chimpanzee is more like an earthworm than a human being, despite the close biological relation of chimpanzees to human beings.

The small genetic difference between humanity and its closest relatives is actually a difference in capacity and potentiality that is indefinitely large, which actually means that it can never be fully measured (Kateb 2011 p. 17).

It is interesting to note that Kateb's intuitive comparison between earthworms, chimpanzees and human beings actually coincides surprisingly well with my own assessment of complexity, implying that the evolution of human culture contributes with as much as half of the total value of complexity. I just hope that my model of the evolutionary process may increase our appreciation of mankind's dignity.

Finally, in pointing out citations in favour of the notion of mankind as a unique and superior species I would like to refer to the last sentence in Dawkins's seminal book *The Selfish Gene* that reads:

We, alone on earth, can rebel against the tyranny of the selfish replicators. (Dawkins 1976 p. 215).

One may wonder why so many scientists so fervently reject the depiction of animal evolution as following a direction towards successively higher levels, whereas lay people, as I have understood, see it as intuitively obvious. As I have pointed out, it seems that as to this issue, scientists refer to the current opinion that there is no measure of evolutionary progress.

Maybe also there is an apprehension that if one accepts to regard different species as living at different levels, one might as well consider different putative human races at different levels; if at all the notion of races is meaningful. I ardently emphasize that the present model of the evolutionary process doesn't endorse such an interpretation. I find support of this statement in a discussion by Dawkins (2004 B) saying that the great majority of human genetic variation is to be found within races, not between them (*ibid.* p. 76). This means that the horizontal lines in the diagram of Figure 6 cannot be interpreted as putative human races. This has also to do with the fact that animal species are reproductively isolated from each other whereas, as to culture, there is no such limitation. On the contrary, many human cultures have always exchanged ideas and knowledge in a way that has made their differences hard to classify. Genes are stuck to their particular species whereas memes are floating freely within and between societies.

CONCLUSION

In the present work, I give an all-embracing perspective on processes of the evolution of life and culture on earth. Thus I see the evolutionary processes as occurring in two dimensions; those of complexity and time. By means of the inclusion of complexity, evolution gets a hierarchical order.

The problem with the concept of complexity is generally seen in the absence of its definition. I have evaded this difficulty by suggesting an operational definition built on a procedure of measuring complexity by means of a combination of empirical data from the evolutionary and developmental processes. In this procedure I made use of the process of condensation of developmental traits, a process that I found to proceed regularly and independently of the haphazard external contingencies. In this way I found that the performed

measurement of complexity revealed a regular and rapidly accelerating growth over a great part of the evolutionary history, explained in part as a result a self-reinforcing feedback process in complexity. In this way the wide-spread though intuitive notion of a rapidly growing pace of evolution is supported.

Natural selection is generally considered as the key process of organic evolution which, according to the common interpretation, adapts populations to their environments, thus producing enduring though irregular evolutionary changes. In the present work, I investigate complementary possibilities of an understanding of the large-scale evolutionary process.

Thus I suggest a new kind of natural selection that diverges from the traditional form in that it acts independently of environmental contingencies. This form of natural selection has its application in the process of individual development that is found to be regularly shortened. Together with the development process, the large-scale evolutionary process is found to follow a simple general pattern.

Furthermore, I have found that natural selection is insufficient in explaining the large-scale course of evolution as characterized by a rapid acceleration of its growth. This feature is instead explained as a result a self-reinforcing feedback process in complexity.

Likewise, I have found natural selection to be insufficient in explaining the human cultural and scientific manifestations of evolution. In these fields I suggest an explanation by application of two processes: a self-reinforcing feedback process and intentional selection.

My analysis of evolution in the light of complexity has led me to the construction of a new form of a Tree of Life, displaying complexity versus time. This illustration of evolution comprises stagnant species as well as the stepwise rapid bursts of novel species implying that the latest emerging species dwells at the highest level of complexity. At present this species is the human species rendering us the position as the summit of evolution on earth.

Chapter 13

NATURAL SELECTION AND DIABETES MELLITUS

Svetlana Shtandel*

V. Danilevsky Institute for Endocrine Pathology Problems
Kharkov, Ukraine

ABSTRACT

Advances in modern medicine enable a change in the tension of intragroup selection in human populations. Thus, implementation of insulin for type 1 diabetes mellitus (DM) treatment considerably lowered the selection tension for this symptom and converted it from the sub-lethal to the one with a lowered adaptability. Increasing variety of type 1 DM and type 2 DM is being observed recently in different populations. Moreover, recently the heterogeneity of type 1 DM and type 2 DM has also been observed. The investigation was aimed to study the influence of the selection on the evolution of DM clinical forms. Global implementation of insulin therapy into type 1 DM treatment caused the prevalent increase of this disease. Currently, there is a positive selection trend for type 2 DM, which is the original cause for the prevalence increase within the population, and the negative one for type 1 DM determines its prevalence within the population approximately on the same level. Intra-population change of gene frequencies, susceptible for type 1 and 2 DM, predetermined the development of such DM clinical forms as LADA (latent autoimmune diabetes in adults). It also resulted in the increasing number of patients with an absolute insulin deficiency of type 2 DM, which is a more complicated form of this DM type. Polymorphisms association, changing the immune response and forming the susceptibility to type 1 (C1858T of the gene *PTPN22*, A49G of the gene *CTLA4*) and type 2 (E23K of the gene *KNJ11* participating in insulin insufficiency formation) with different DM forms illustrates the result of decreasing the selection tension against type 1 DM after insulin therapy implementation into the public health services practice.

Keywords: Type 1 and 2 diabetes mellitus, latent autoimmune diabetes of adults, natural selection, relative adaptability, prevalence in population

INTRODUCTION

Population dynamics factors that change the gene frequencies include: a) recurrent mutations; b) natural selection; c) migration and d) casual fluctuations [1]. It is known, that the genes and chromosomes mutations are the unique source of all genetic variability, although frequency of their occurrence is very low. As the mutations process is very slow, they by themselves change the population genetic structure with a very low speed [2]. Selection is the principle driving force of the evolution. Modern definition of selection is generally used as a differential reproduction of various genes variants, i.e., carriers of certain traits, have more chances to survive and have geniture, than the carriers of other traits [2]. The central concept of the selection theory is adaptability. Only the different reproduction speed of individuals with various genotypes is important for selection. The reproductive ability of a particular genotype in comparison with the norm is called the Darwinian adaptability of this genotype [1]. The adaptability level depends on the decrease of an individual viability and because of those or other pathologies, impossibility to survive till the reproductive age, and also the fertility decrease of any individual [3].

I. I. Shmalgauzen, who has contributed greatly into the problem of evolution studying and search of its solving, wrote: "As phenotypes are the carriers of viability and objects of the natural selection – the individual development course could not bur influence the evolution... the most important thing - an organism as such with its active struggle for its life is not visible in the genetic theory of natural selection." And, according to I.I. Shmalgauzen, phenotypes are the objects of natural selection, or, it can be said, that natural selection influences the phenotypes. Purpose of the thesis about selection influence on phenotypes assumes the necessity of relation between the selection and the organism properties [4].

Natural selection concept is a discordant problem of evolutionary human genetics. Despite the popularity of a hypothesis of "neutral evolution," most of the scientists believe that selection has played the principle role in evolution of species and has generated all the biological diversity of human populations [5]. While considering the large human populations, the following types of selection are distinguished: 1) intragroup, based on inter-individual adaptability differences (differential reproduction of genotypes) and 2) intergroup, which takes into consideration the differences in average adaptability of populations (differential natural growth of particular groups) [6]. There is a couple of difficulties, caused by applying the biological adaptability concept in respect to a human, measured by number of viable geniture, which does not consider the human society social organization specificity. The modern medicine allows to "correct" the phenotype manifestations of some hereditary pathologies, to create the adaptive environment for the genotypes, which in more severe constraints would be eliminated by selection, and in thus to increase their adaptability. This phenomenon was called "a dysgenic effect of medicine" [7, 1]. Change of the intragroup tension - for example, by successful treatment of multifactorial diseases (MFD) - leads to change of the distribution curve of the disease susceptibility and, hence, to its distribution increase. However, the quantitative estimation of such changes is complicated.

In the modern literature, the issues of selection in human populations [7-9] were actively studied. For this purpose, the methodology of selection intensity estimation (I_t) and its components, bound with differential pre-reproductive mortality (I_m) and differential fertility (I_f), is applied (developed by J. Crow [10]). However, meaning of selection in human

populations is being disputed till now. Thus, some authors assume, that selection in the modern urbanized populations is practically absent [11], the others - that available data do not demonstrate the selection weakening in the modern urban populations [12]. Up to half of human gene pool is not reproduced in the succeeding generation because of the embryos death, fetal deaths, neonatal mortality, death-rate before reproductive age, celibacy and sterile marriages in developed countries [13, 14]. Factors of economic progress and social development of the society influence the selection orientation and intensity in populations, but do not stop its action. In different populations the components of differential fertility and differential mortality considerably differ from each other [8, 15-17].

It should be noted that on different stages of mankind history, selection intensity and orientation were exposed to considerable fluctuations. Ancient populations of hunters and collectors were characterized by a moderate level of pre-reproductive mortalities ($I_m = 0.58$) and fertility (5-6 descendants; $I_f = 0.34$), selection intensity ($I_t = 1.11$), which were not changed significantly during the time [6]. Selection intensifying was noticed in populations of the ancient farmers when the population density increased. Maximal values of Crow indexes, known from all published data, were observed at early stages of urbanization. In the end of XIX century in the Polish community of Pittsburgh (USA) the differential mortality component reached 2.98 (75% of children did not survive till the reproductive age), the fertility component reached 0.99, and the index of total selection was 6.92. In Moscow at the same time, the pre-reproductive mortality reached 60.0%, and the index of total selection was 3.15 [6, 8, 13]. Such high values of pre-reproductive mortalities were explained by a high mortality from infectious diseases, high population density, absence of medical aids and severe life conditions of the majority of citizens. Only in XX century, as a result of social progress and successes of public health services, there was a sharp reduction of pre-reproductive mortalities in the developed countries. Simultaneously this process was accompanied by birth rate decreasing [6, 16]. Growth of population genetic burden is a predicted consequence of the selection intensity depression [6, 18]. Numerous studies, devoted to neonatal mortality rising, increasing of individuals part with various congenital defects of development and immune system, mental and cardiovascular diseases were confirmed this thesis [12].

Particularly, thanks to development of medical practice, in economically developed countries, selection by elimination of nonviable individuals moves towards the early stages of ontogenesis. However, the biological selection on the later stages of ontogenesis in these countries is going on, though not by means of elimination, but in the form of retardation. After all, it is obvious, that self-preservation means both individual surviving, and surviving in the sequence of generations. Thus, for realization of biological selection it is enough that some individuals survive more successfully, producing more geniture than others [19].

One of the forms of selection action is elimination. On the average, in humans approximately 50% of zygotes are eliminated, 15% of embryos till birth and near 5.0% of children dye at birth, about 3% more do not survive till maturity [20, 21]. Biological selection by elimination takes place also at the later ontogenetic stages, especially in underdeveloped countries, in which at the centuries border there lived 4.4 billion persons, 3/5 of which lived without elementary hygienic conditions, and 1/5 had no access to modern medicine [21]. In such conditions, biological selection by elimination is unviable (for example, selection on the infections resistance).

From everything we know about selection in modern society, one can make two conclusions: 1) Biological selection in human population really reacts by means of selective

elimination and inhibition. 2) However, in society there is no biological selection as an independent, determinative factor of evolution, irrespective of any social patterns. With appearance of labor, the biological selection is not getting weaker, but changing its final orientation, submitting to the social factors and social production. Finally, the social production realities define competition and selection course, elimination and inhibition in the modern society, i.e., are expressed as social selection which is carried out on “basis” of biological selection and consequently has biological consequences for society, biological “equivalents” [22]. Depending on the social production development level, the biological selection acts either via elimination at all stages of ontogenesis, or more generally, in the form of inhibition. Negative consequences of selection weakening through elimination, which are expressed in the economically developed countries in accumulation of “genetic burden,” are corrected by the social production: development of medical practice [23] and “incoming of fresh blood” by means of immigration.

One of the basic achievements in biology is a new clear recognition, that the following is required for all biological traits: a) to explain precisely how the trait “works”; to explain from the evolutionary point of view, for what the trait exists [24]. Medical researches concentrated on features of the organism functioning and on immediate factors, explaining why in some people disease occurs, and in others - not. The Darwinian medicine states the other, evolutionary question. Why every organism, in more or less extent is susceptible for diseases? For what appendix and wisdom teeth exist? Why our coronal arteries are so narrow? Why the mammary gland cancer occurs so often now? From the first sight, the answer seems to be simple. Natural selection is a random process; therefore it cannot lead any trait to the highest perfection [25, 26]. However, the latest, more careful analysis revealed some other reasons, caused by evolution, of the organism remaining vulnerable to diseases: new environmental factors, our organism is not adapted for; the compromise construction, which makes us more vulnerable to diseases, but induces the general benefit; microorganisms, which evolve faster, than people do; and also the defensive traits, such as pain and cough, which are similar to illness, but actually they are the protective mechanisms, generated in the course of natural selection. There is a number of works, studying how the evolutionary approach creates the base for MFD understanding [27, 28].

It is known that the food consumption was irregular at early stages of human development. In those conditions the possibility to form deposits of fat tissue and carbohydrates in the case of their big consumption was an important adaptive mechanism, allowing to survive in the periods of poor nutrition and starvation. It is also essential, that at the first stages of human development, human’s life was characterized by an exact allocation of men and women roles. Men went for hunting; women stored the hearth side, gave birth and brought up children. Thus, men were supposed to have stronger muscles that caused the primary development of the muscular tissue. For geniture feeding, women had to be adapted to keep energy reserves, i.e., to have developed fatty tissue that served as a protection of newborns against starvation at the time of poor nutrition. During later periods, food obtaining was carried on no longer by hunting, but by development of agriculture and cattle breeding, that also demanded great physical expenses. There was no abundance of nutrition for the majority of people. The certain balance between caloric intake and energy consumption was maintained. In a very short time period, from the point of view of evolution, the major part of mankind started to get plentiful nutrition without starvation periods and muscular energy expenses, related to severe life conditions. One can assume that a modern human, and firstly a man, who usually has less developed fatty tissue

in comparison to a woman, obtains ischemic heart disease and myocardial infarction as a payment for satiety in combination with his muscular energy small demand [29].

Wide distribution of a particular genotype in a population takes place in the case when this genotype gives to its owner selective advantages against the individuals not possessing it, for example, the ability to survive in extreme conditions, in particular in conditions of hunger. In conditions of constant food excess, insulin apparatus is continually under increased loading due to changes in balance between caloric intake and energy consumption. As per J.V. Neel theory, as it was mentioned above, it is presupposed [28], that there are special genes (thrifty genes), allowing a person to use effectively the limited food resources, that leads to DM development in conditions of nutrition abundance. This theory has found its confirmation in works of W. Knowler et al. [30] and P. Zimmet et al. [31], who showed the rapid increase of 2 type DM frequency among the indigenous population of Northern America and Pacific Islands in conditions of urbanization and nutrition abundance.

Globalization processes, existing in modern society, lead to increase of outbreeding, panmixia, genes mixing, and segregation burden increase. Significant part of a genome is invariable, monomorphic and conservative. This genome fraction is vitally important and any mutation in it is eliminated by natural selection. Along with this, the variable part of a genome is functionally less important. Therefore, variability, so-called genetic polymorphism, is the minor variability, connected with the adaptation processes and accommodation to certain environmental conditions. Levels of individual heterozygosis in representatives of the same or different populations can considerably differ [32]. In total, the whole genome includes about 4 million of such substitutions (polymorphisms). About 2.5 million of polymorphisms account for sense, coding part of a genome. Genetic polymorphisms spectra depend on geographical conditions, diet, racial (ethnic) belonging, etc. and they are provoked by the natural selection. In certain conditions, they can contribute to development of specific diseases or, on the contrary, inhibit them [33].

Thus, the problem of selection influence on MFD prevalence variation and evolution of its clinical forms is not studied enough and leaves a great number of questions opened.

The modern level of medicine allows to “correct” the phenotypical manifestations of many hereditary pathologies and create an adaptive environment for genotypes, which, because of any adequate therapy absence, would be eliminated by the natural selection, and, thus, to increase their adaptability. In due time, this phenomenon has been called “the dysgenic effect of medicine” [1, 7]. Selection of the polygenic diseases belongs to the intragroup selection. Change of the intragroup selection tension (for example, by successful MFD treatment) causes a change of the distribution curve of susceptibility to this disease and, consequently, increases its prevalence. However, the quantitative estimation of such changes is complicated. From the point of view of population genetics, the hereditary diseases are divided into diseases, associated with impaired reproductive ability, and diseases, where the reproductive ability is not impaired, either because of the defects insignificance, or because they are manifested only after the reproductive period completion. Frequency and prevalence of the first group of diseases are determined by frequency of the corresponding mutations occurrence. The other situation takes place in case of diseases, not affecting the reproduction [1]. This group includes the most widespread MFD, such as DM, schizophrenia, cardiovascular diseases, obesity etc. However, till now, the selection of diseases, not affecting the reproduction, in the conditions of “the dysgenic effect of medicine” is practically not being studied, and the major part of works

is devoted to either the intergroup selection, or the inborn hereditary pathologies selection [34-36].

DM both 1, and 2 types are polygenic MFD [37-42]. According to J.V. Neel hypothesis [28], type 2 DM occurs as a result of special genes existence (thrifty genes), allowing men to use effectively limited food resources, which lead to the disease development in the abundance of food conditions. Thus, if this was the case, type 1 DM was a sub-lethal trait before the insulin therapy introduction into the health care practice. This type of DM is an autoimmune disease, in the course of which the acute lymphocytic insult leads to pancreatic β -cells destruction with subsequent development of the absolute insulin insufficiency [43]. Beginning at pre-pubertal or pubertal age, not supported by the insulin therapy, resulted with the lethal outcome approximately in 0.5-1 year after manifestation. Thus, possibility to leave any genotype was practically reduced to zero. Global implementation of the insulin therapy at the end of 40th – beginning of 50th years into the health care practice has prolonged patients' life, allowed to keep genotype, which resulted in weakening of the selection tension and led to the disease prevalence increase within the population.

Nowadays, a rapid growth of type 2 DM prevalence [44] becomes perceptible worldwide. Besides the environmental factors, promoting growth of this disease prevalence, most likely, the increase of population frequency of gene complexes of susceptibility to this type of diabetes is also necessary for such increasing of type 2 DM frequency in populations. In addition, there should be noted the ubiquitous spreading of type 2 DM severe clinical variant with development of the absolute insulin insufficiency (AID), caused by depletion of residual secretory function of pancreatic β -cells and their subsequent apoptosis [45]. According to the literature, approximately 40% of patients with type 2 DM require the insulin therapy (IT) [46]. There was shown an increased family accumulation of type 2 DM in patients with type 2 DM with AID, and the genetic analysis results demonstrated that the long non-insulin-dependent (LSDID) form can formally be considered as “a less burdened” one, and type 2 DM with AID - as “a more burdened” one [47].

Is it also impossible to ignore the considerable prevalence among the clinical forms of DM variants (2-12% of all the cases) of such its form as the latent autoimmune diabetes of the adults – LADA, whose manifestation is similar to type 2 DM. The subsequent slow development of autoimmune aggression against the pancreatic β -cells, insulin-dependence and necessity of the insulin therapy became the foundation for distinguishing of this disease form as the type 1 DM subtype in classification of 1999 [48]. On the basis of the investigation of patients with the determined diagnosis of type 2 DM and availability of the auto antibodies against GAD, several authors concluded, that this form of DM has an autoimmune nature, but differs from type 1 DM by the rate of the absolute insulin dependence development and by prevalence of alleles, predisposed to type 1 DM [49, 50]. Genetic analysis of this DM form, which was carried out by us, has shown its genetic independence and considerable number of common genes in determination of clinical variants of the disease course (the % of common genes with type 1 and 2 DM was 65.3 and 66.1%, respectively) [51]. Such heterogeneity of DDM clinical variants of DM course can be the consequence of the global implementation of insulin into the health care practice, which sharply reduces the selection tension against type 1 DM that led to increasing of prevalence of gene complexes of susceptibility to the 1th type of disease within the population.

The aim of the investigation was to study the selection influence on heterogeneity of DM clinical forms and the prevalence dynamics within the population.

MATERIALS AND METHODS

To accomplish the assigned tasks, the obstetric anamnesis and presence of polymorphisms of C1858T of *PTPN22*, 49A/G of *CTLA4* and E23K *KCNJ11* genes were studied in DM patients, treated in V. Danilevsky Institute for endocrine pathology problems in 1997 – 2014.

The obstetric anamnesis data of 2106 women after 45 without any symptoms of the investigated diseases were used as a control group. The obstetric anamnesis data are obtained during examinations on different enterprises in Kharkov.

To determine the relative adaptability parameters and to calculate the selection coefficients, the data of obstetric anamnesis were used. The latter included the number of childbirths, pregnancies, spontaneous abortions, extra-uterine pregnancies, survived and deceased geniture till age of 25. It was studied either by questioning or by the hospital histories of the women with completed reproductive period (aged after 45). The number of the investigated women is represented in Table 1.

The determination of C1858T polymorphism of *PTPN22* gene was carried out on 85 patients with type 1 DM, 140 patients with type 2 DM, 115 persons with LADA and 11 healthy Kharkov citizens. The data on C1858T of *PTPN22* gene polymorphism of 242 healthy Kharkov citizens and 296 patients with type 1 DM, received as a result of the inspection in 2004, was kindly submitted for the further analysis by the research worker of Institute of parasitology and biomedicine (Granada, Spain), Maria Ivanovna Fedets. The author expresses a deep gratitude to M.I. Fedets for the data provided. The analysis results were published in the papers of M.I. Fedets as a co-author. Determination of 49A/G polymorphism of *CTLA4* gene was carried out on 64 patients with type 1 DM, 127 patients with type 2 DM, 109 persons with LADA and 75 healthy Kharkov citizens. Determination of E23K polymorphism of *KCNJ11* gene was conducted on 47 patients with type 1 DM, 101 patients with type 2 DM, 83 persons with LADA and 44 healthy Kharkov citizens. Characteristic of the investigated persons is presented in the Table 2.

The “accumulated” population frequency of type 1 and 2 DM in Kharkov region was calculated on the basis of data about patient’s age at DM beginning and a proband age, contained in 1303 histories (857 – type 2 DM, 446 – type 1 DM), available in the district hospitals, as well information about the overall population of the district [52].

Table 1. Characteristics of the women with the investigated obstetric anamnesis

	Control	Type 1 DM	Type 2 DM
N	2106	281	538
Age (years)	57.47 ± 0.16	52.52 ± 0.53	60.62 ± 0.46
Age of the DM beginning (years)	-	20.79 ± 1.84	43.51 ± 0.50
BMI, kg/m ²	24.08 ± 0.12	23.58 ± 0.36	30.64 ± 0.60
WHR	0.76 ± 0.02	0.71 ± 0.06	0.90 ± 0.01

Table 2. Characteristics of persons, whose C1858T of *PTPN22*, 49A/G of *CTLA4* and E23K of *KCNJ11* genes polymorphisms were analyzed

	Control	Type 1 DM	Type 2 DM	LADA
Age (years)	35.40 ± 0.90	37.10 ± 0.70	53.94 ± 0.47	52.19 ± 1.45
Age of the DM beginning (years)	-	23.15 ± 0.94	44.53 ± 0.51	45.80 ± 1.34
Age of the insulin therapy beginning (years)	-	23.15 ± 0.94	53.14 ± 0.81	48.06 ± 1.37
Duration of effective per oral anti-hyperglycemic therapy (years)	-	-	10.48 ± 0.43	2.57 ± 0.32

Sampling was formed according to the initial visit in 2007. The indexes of «accumulated» population frequency of type 1 and 2 DM of 1973 were estimated based on the data about age of DM beginning from 682 clinical records (402 type 2 DM and 280 – type 1 DM), received from archive of Kharkov antioiter dispensary during 1973. The data from 213 hospital histories, which were also received from archive of Kharkov antioiter dispensary, were used for calculation of this index for type 1 DM in 1995. The sampling was formed according to the initial visit of Kharkov antioitrogenic clinic in 1995. The structure of the clinical variants of type 2 DM course both in 1984, and in 2007 was determined from the hospital histories data, received from the archive of Kharkov antioiter dispensary and V. Danilevsky Institute of endocrine pathology problems. The dynamics of DM prevalence was estimated according to the official statistics data [52-58].

Relative adaptability (w) and selection coefficient (s) were calculated for selection direction determination [2]. Thus, relative adaptability (w) was estimated as a result of fertility and survival rate, and $s = 1 - w$. The selection direction was determined as difference between selection coefficients within the population and among the patients ($\Delta s = S_{\text{population}} - S_{\text{patients}}$).

The fertility component was determined by calculation of an average geniture number per one woman, for ill and healthy women, with the subsequent division of an average geniture number per each group by a greater average geniture number in comparison groups.

Survivability component was determined by calculation of the geniture part that survived till 25 in the comparison groups with subsequent division of the survived geniture part for each group on a greater part of the survived geniture in comparison groups.

Values of «accumulated» population frequency were calculated according to [59] on the following formula:

$$q_g = q_0 + q_n \prod_{i=0}^{i=n-1} (1 - q_i),$$

where $q_0, q_1, q_2, \dots, q_n$ – values of morbidity accordingly in the initial (q_0), 1, 2, ...n age-dependent interval.

$$q_n = \alpha_{n+s} p_{n+s}$$

where α_{n+s} is a part of persons, who have got ill at the age of n among the patients, whose age was $n+10$ years at the moment of research; p_{n+s} is the disease prevalence among the persons of age of $n+10$.

DNA extraction was conducted on whole blood, using DNA extraction set “DNK-sorb-V” kit (Moscow, the Russian Federation).

C1858T polymorphism of *PTPN22* gene is determined by the polymerase chain reaction using *RsaI* restrictase [60]. A 218-bp fragment containing the single nucleotide polymorphism C1858T of *PTPN22* gene was amplified using direct ACTGATAATGTTGCTTCAACGG and reverse TCACCAGCTTCCTCAACCAC primers. The reaction mixture contained 20 ng of genomic DNA, 1.2 µl of 10x PCR buffer, 1.2 µl of dNTP (1.25 mmol/l), 0.3 µl of each primer (20 pmol/µl), 0.6 µl of DMSO, and 0.1 µl of *Taq* polymerase (“Sibenzyme” company) in a 12-µl reaction mixture. Amplification conditions: initial denaturation for 2 min at 94°C, followed by 35 cycles of 94°C for 30 s, 30 s at 60°C, and 30 s at 72°C and an additional extension of 2 min at 72°C. Amplification product (12 µl) was incubated using 10 units of *RsaI* restrictase (“Sibenzyme” company) at temperature 37°C for 12 h. Restricted products were electrophoresed on 2.5% agarose gel. The mutant 1858T allele loses the restriction sequence and consists of one 218 bp fragment. 1858C allele restriction results in two fragments of 176 bp and 46 bp.

A49G polymorphism of *CTLA4* gene was amplified with the help of direct 5'-GCTCTACTTCCTGAAGACCT and reverse AGTCTCACTCACCTTTGCAG primers. The reaction mixture contained 25 ng of genomic DNA, 2.5 µl of 10x PCR buffer, 0.6 µl of dNTP (2.5 mmol/l), 0.3 µl of each primer (20 pmol/l) and 0.2 µl of *Taq* polymerase (“Sibenzyme” company) in 25 µl of the reaction mixture. Amplification conditions: initial denaturation for 4 min at 94°C, the following steps 58°C - 45 s, 45 s at 72°C, and 45 s at 94°C (30 cycles) and the final extension for 4 min at 72°C. Amplification product (10 µl) was incubated with the restriction enzyme *BbvI* at 65°C for 1 h. Normal allele 49 A loses the restriction sequence and consists of a 162 bp fragment, the mutant 49G allele restriction produces 88 bp and 74 bp fragments [61].

E23K polymorphism of *KCNJ11* gene was amplified with the help of direct GAATACGTCCTGACACGCCT and reverse GCCAGCTGCACAGGAAGGACAT primers. The reaction mixture contained 25 ng of genomic DNA, 2.5 µl of 10x PCR buffer, 0.6 µl of dNTP (2.5 mmol/l), 0.3 µl of each primer (20 pmol/l) and 0.2 µl of *Taq* polymerase (“Sibenzyme” company) in 25 µl of the reaction mixture. Amplification conditions: initial denaturation for 3 min at 95°C, the following steps 95°C – 1 min, 1 min at 62°C, and 1 min at 72°C (35 cycles) and the final extension for 5 min at 72°C. Amplification product (10 µl) was incubated with the restrictase *Ban II* at 37°C for 2 h and 65°C for 10 min. The mutant 23K allele loses the restriction sequence and consists of a 218 bp fragment. 23E allele restriction results in 178 bp and 40 bp fragments [62]. Evaluation of relative risk of the disease development at polymorphism carriage (Odds ratio) was conducted according to [63].

Statistical analysis. Data are expressed as either mean±SD or percentages. The normality of the distribution of variables was tested with the Kolmogorov-Smirnov test. Comparison of variables between the control and diseases groups was carried out with the Student's test or the chi square test. Comparison of percentage variables was carried out with the Fisher test. A p-value equal to or less than 0.05 was considered to be statistically significant.

RESULTS

The obstetric anamnesis data, which formed a basis for calculation of relative adaptability indexes, are presented in Table 3. The compared groups of healthy and type 1 DM women differed by number of pregnancies. With the similar women behaviour related to the family planning, this fact might be an evidence of selection effect on the impregnation stage. Unfortunately, this question in the investigated groups remained opened, that does not allow to make an unambiguous conclusion about difference in influence of natural selection among healthy women and patients with type 1 DM during impregnation. Number of pregnancies in healthy women significantly exceeds those of type 1 DM, though the average number of childbirth is approximately equal within the population and the investigated groups. This phenomenon can be explained by the fact that women with this diagnosis, knowing about the problems, associated with pregnancy with type 1 DM, are doing their best to maintain the pregnancy.

The values of spontaneous abortions and extra-uterine pregnancies in the compared groups had no significant differences. The obtained results can prove that on the embryogenesis stage there was no selection influence on 1 and 2 type DM. Women distribution by number of childbirths is presented in the Table 4.

The obtained data show the significant distribution difference in childbirths number of healthy women and women with DM. Thus, the significant difference in distribution of childbirths number between women with type 1 and 2 DM is also noted ($\chi^2 = 15.319$; $df = 9$; $p = 0.004$). It is shown that number of women among patients with type 1 DM, who had two and more childbirths, was significantly higher, than of the healthy ones ($\chi^2 = 34.770$; $df = 1$; $p = 0.000$) – 45.68 and 42.40%, respectively. Analogous result was observed also at type 2 DM, ($\chi^2 = 28.678$; $df = 1$; $p = 0.000$) – number of type 2 DM patients and healthy women who had two and more childbirths, was 55.39 and 42.40%, accordingly. According to Table 3, patients with type 2 DM left more children, than the healthy ones and woman with type 1 DM. It should be noted, that women, who have deceased till 45, were excluded from the sampling of patients with type 1 DM because it could overstate some indexes of average number of childbirths in this group.

Table 3. Fertility indexes and geniture survival rate

Parameter	Population	Type 1 DM	Type 2 DM
Pregnancy, ($\bar{x} \pm S_x$)	4.06 ± 0.07	$2.80 \pm 0.17^*$	4.01 ± 0.11
Childbirth, ($\bar{x} \pm S_x$)	1.41 ± 0.02	1.47 ± 0.06	1.59 ± 0.04
Spontaneous abortions, ($\bar{x} \pm S_x$)	0.08 ± 0.01	0.12 ± 0.02	0.10 ± 0.02
Extra-uterine pregnancies, ($\bar{x} \pm S_x$)	0.03 ± 0.01	0.03 ± 0.01	0.03 ± 0.01
Childless women, (%)	12.35 ± 0.72	13.88 ± 2.07	10.24 ± 1.31
Children, survived till 25, (p_s)	0.972	0.877*	0.966
Children, deceased till 25 (p_s)	0.028	0.123*	0.034

Remark* - significance of differences in comparison to the population ($p < 0.001$).

Table 4. Women distribution by number of childbirths

Childbirth number	Control, n = 2106	Type 1 DM, n = 281	Type 2 DM, n = 538
0	260	39	55
1	953	113	185
2	735	96	243
3	125	23	44
4	17	9	8
5	6	1	0
6	4	0	1
7	4	0	1
8	0	0	1
11	1	0	0
χ^2		18.236	36.746
P		0.001	0.000

Analysis of the geniture survival rate in healthy women and mothers with type 2 DM did not demonstrate any high mortality among patients' geniture, being a little lower than in children of healthy women (Table 3). At the same time, analysis of the geniture survival rate in women with type 1 DM and healthy women registered an increased mortality among the geniture of women with type 1 DM in comparison to the children of the healthy women. The obtained data are consonant with the data on increased perinatal mortality in newborns, whose mothers had DM (without diabetes types separation), presented in literature [64, 65].

Indexes of relative adaptability and selection coefficients, calculated based on the obstetric anamnesis, are shown in Table 5. The presented results demonstrate the relative adaptability reduction in the group of patients with type 1 DM.

Table 5. Relative adaptability and selection coefficients

Group	Relative adaptability (w)			Selection coefficient (s)
	Fertility component	Survival rate component	Total adaptability	
Population	0.959	1.000	0.959	0.041
Type 1 DM	1.000	0.901	0.901*	0.099*
Population	0.887	1.000	0.887	0.113
Type 2 DM	1.000	0.988	0.988	0.012*

Remark* - significance of differences in comparison to population ($p < 0.001$).

Selection coefficient value in type 1 DM group is more than twice higher, than among the healthy women of Kharkov ($F = 13.22$; $p < 0.001$), that shows existence of selection against ($\Delta s = -0.058$) this DM type nowadays (Figure 1).

Due to global application of the insulin therapy into health care practice since the beginning of the 50th years of the 20th century, the selection tension against type 1 DM was reduced. For rather short period of time, it has decreased practically from 100.0% (patients left no geniture) to 9.9% that, certainly, had to affect the population frequency of the disease.

Figure 1. Selection direction of type 1 and 2 DM.

Changes of type 1 DM prevalence among the population of Kharkov area from 1973 to 2007 are presented on Figure. 2.

As expected, because of global implementation of insulin into the therapy of 1 type disease in the 50th years of the last century, approximately one generation later (from 1973 to 1995) the prevalence of type 1 DM has grown – from 0.16 to 0.32% in Kharkov region ($F = 1633.47$; $p < 0.001$). From 1995 till 2007 growth of this disease type prevalence was practically stopped and was 0.32-0.36%. And in recent years from 2009 to 2013, the decrease in population prevalence of similar disease from 0.36 to 0.26% is even noted. It can be explained by the fact that growth of genes frequencies of susceptibility to 1 type DM, caused by the insulin therapy introduction, reached its maximum and now the reduced adaptability of this trait leads to decreasing of its population frequency due to low genotype survival rate.

It should be noted, that in official statistical collections, which data were used in our work, LADA is considered as a variant of type 1 DM and number of patients with this form is summed up with number of patients with a classical type 1 DM. It can also influence the indexes of type 1 DM prevalence.

Figure 2. Type 1 and 2 DM prevalence in population of the Kharkov region in 1973-2013.

At calculation of prevalence, as the relation of patients number to the population number without accounting the demographic population structure, the prevalence increase can be caused by the population aging, because in the older age groups, as it was before, during the pre-insulin era, the previous cases are accumulated. For a more exact characteristic of dynamics of disease prevalence within the population, the age disease estimates are used, based on which «the accumulated population frequency» is calculated. To estimate the dynamics of DM occurrence probability during life, in population of Kharkov region, the indexes of «accumulated population frequency» were calculated for 1973, 1995 and 2007. The age indexes of «accumulated population frequency» of type 1 and 2 DM among the population of Kharkov region are presented on the Figure 3.

Figure 3. Indexes of «accumulated population frequency» of type 1 and 2 DM among Kharkov region citizens, %.

For type 1 DM, some growth of «accumulated population frequency» from 1973 to 1995 by 1.86 time is shown ($F = 0.116$; $p > 0.05$), and even its small decline from 1995 to 2007 from 0.345 to 0.343% ($F = 0.0001$; $p > 0.05$) is shown.

Existent selection against type 1 DM gives the grounds to assume that it is not necessary to expect a rapid growth of type 1 DM prevalence in populations.

Data, provided in Table 5 indicate the higher relative adaptability of patients with type 2 DM in comparison with a healthy phenotype. The value of selection coefficient in type 2 DM was much lower, than in the healthy women of Kharkov region ($F = 93.06$; $p < 0.001$). Thus, the conducted research shows that a positive orientation of type 2 DM selection (Figure 1) takes place ($\Delta s = 0.101$) – patients leave more geniture, than the healthy people, at their practically identical survival rate (Tables 3, 4). This, in its turn, increases the frequency of susceptibility to this type of disease genes in the population.

The obtained data are confirmed by the evidence on a significant increase (almost four times) of type 2 DM prevalence in population of Kharkov region ($F = 31518.6$; $p < 0.001$) for thirty four years in 1973-2007 (Figure 2.).

From 1973 to 2007 the «accumulated population frequency» of type 2 DM increased in 2.75 times ($F = 5.21$; $p < 0.05$). Therefore, the selection in favor of type 2 DM allows to forecast the further growth of this type of disease prevalence in populations and, from genetics point of view, explains the reasons, promoting a rapid growth of this type DM prevalence in the world.

The increase of frequency of both 1 and 2 type DM susceptibility genes in the population, caused by a positive selection direction (for type 1 DM to the middle of 90th years of the 20th century), can also be reason, causing the clinical heterogeneity of this disease.

Such aspect of selection action is confirmed both by the features of genetic heterogeneity of type 2 DM, and dynamics of clinical forms structure in all cases of type 2 DM. Recently, ubiquitous growth of specific severity of the disease clinical course with development of AID

among all patients with type 2 DM [46] is noted. So, compared to 1984, the number of patients with AID among all patients with type 2 DM were up to 22.65% in Kharkov region, in 2007 this index has grown to 33.48% ($\chi^2 = 10.729$; $p = 0.001$). The conducted researches [47] have shown that out of two studied forms of type 2 DM, one is more complicated. According to the genetic analyses results, the LSNID form can possibly be formally considered as “a less complicated,” and type 2 DM with AID - as “a more complicated.”

Hence, the population frequency increase of genes of susceptibility to type 2 DM, caused by a positive selection direction, raises probability of their high concentration in a proband, and thus promoting the increase of AID prevalence among all cases of the disease.

The frequency increase of genes of susceptibility to 1 type disease became the possible effect of selection tension decrease against type 1 DM, caused by introduction of insulin therapy into the health care practice. Combination of population frequency growth of genes of susceptibility to type 1 and 2 DM and increase in probability of their occurrence in a proband has defined appearance of such DM form, as LADA, among all variants of the disease course. This is evidenced by the genetic analysis results, which have showed that inheritance of LADA is described by the polygenic threshold model parameters, in its inheritance the essential role belongs to the genetic factors, there are nonlinear genetic interactions, and influence of genes number is possible with the expressed effect in determination of this DM form. Existence of a large number of common genes of susceptibility to type 1 and 2 DM and LADA (65.3 and 66.1%, respectively) defines the features of clinical course of this DM form - manifestation is similar to type 2 DM: the subsequent fast development of autoimmune aggression to the pancreatic β -cells, insulin-dependence and insulin therapy necessity [51].

Taking into account, that modern level of researches embraces not only the genetic analysis data, but also molecular genetics methods, we studied the distribution features of the single nucleotide polymorphisms genes, determining the susceptibility to both type 1 and 2 DM. Taking into consideration, that the HLA system antigens, which generally determine susceptibility to type 1 DM, are strongly linked and badly combined, it was reasonable to study the immune response genes polymorphisms, which play the secondary role in type 1 DM development, localized on different chromosomes and which are well combined in the population in the process of crossing. As an example of such polymorphisms, distributions of mutations of C1858T of *PTPN22* gene and 49A/G of *CTLA4* gene in the patients with type 1 and 2 DM, LADA and healthy Kharkov citizens were studied.

The gene *PTPN22* (protein tyrosine phosphatase non-receptor type 22) is located on the 1p13.3-p13.1 chromosome. This gene encodes the lymphoid-specific LYP phosphatase, which suppress the T-lymphocytes activation. Two variants of *PTPN22* gene - C1858 and T1858 - differ by an important part of amino-acid sequence, which is responsible for LYP association with Csk-kinase (negative regulation). When in the 620th position (T1858 allele) arginine is replaced by tryptophan, the connection with Csk-kinase is not provided. It leads to T-lymphocytes signal function disorder and promotes the development of autoimmune diseases susceptibility, in particular, to type 1 DM [66]. Today it is known, that C1858T polymorphism of *PTPN22* gene is associated with type 1 DM in many world populations: in Ukrainian [67], Italian [68], Swedish and Finnish [69].

The *CTLA4* (cytotoxic T-lymphocyte associated antigen-4) gene also defines the susceptibility to type 1 DM. It is localized on the chromosome 2q33, between two T-lymphocytes genes-activators: the receptor activator gene (CD28) and gene inducing the costimulant (ICOS), contains 4 exons and three introns. The receptor isoform (full-length

isoform-flCTLA4), synthesized in the activated T-lymphocytes is coded by 4 exons: the leader protein is coded by the exon 1, the ligand-binding protein – by the exon 2, the membrane-spanning domain – by the exon 3 and the cytoplasmic domain – by the exon 4. More than 30 points of the mono-nucleotide substitutions in different areas of *CTLA4* gene are known. One of important mono-nucleotide substitutions is a single nucleotide polymorphism 49A/G in the first exon (replacement of adenine by guanine in the 49th position causes replacement of threonine by alanine in the 17th codon of amino-acid sequence of the leader peptide), leading to decrease of CTLA4 protein functional activity. It is established, that the protein product of *CTLA4* gene takes part in T-lymphocytes activity regulation and plays the important role in the autoimmune processes development. [70]. Researches of different populations have revealed both availability [71-76] and absence of [77-79] the associations of type 1 DM with 49A/G polymorphism of *CTLA4* gene.

Among the single polymorphisms, determining the development of susceptibility to type 2 DM, it was logical to investigate the mutation, which is responsible for development of insulin insufficiency in a person. Polymorphism of E23K of *KCNJ11* gene belongs to such mutations. *KCNJ11* gene is localized on the 11th chromosome in area of p15.1. This gene encodes synthesis of Kir6.2 protein (Potassium inward rectifier 6.2), which is a part of the potassium channel in cells, capable to activation, and creates pores for transportation of potassium ions with the cells. The channel closing is necessary for insulin secretion by β -cells. Majority of mutations of this gene are missens-mutations, which have the dominant-negative effect, leading to decreasing of IK1 stream, reduction of repolarization and increase of action potential duration. This polymorphism takes part in the insulin insufficiency development in patients with type 2 DM and is associated with its development in various populations [80].

Table 6. Frequencies of genotypes alleles of C1858T polymorphism of *PTPN22* gene in DM patients and healthy Kharkov citizens

Table 7. Distinctions in frequencies of genotypes and alleles of C1858T polymorphism of *PTPN22* gene in DM patients

Compared groups	Index	χ^2	Significance of differences (p)
Type 1 DM – type 2 DM	Genotype: C/C	0.362	0.547
	C/T	0.877	0.349
	T/T	0.150	0.698
Type 1 DM - LADA	Genotype: C/C	5.466	0.019
	C/T	0.818	0.366
	T/T	5.257	0.022
LADA – Type 2 DM	Genotype: C/C	1.906	0.167
	C/T	0.009	0.922
	T/T	4.741	0.029

The comparative analysis of genotypes distribution with C1858T of *PTPN22* gene polymorphism among all compared groups (Table 6) revealed the statistically significant difference in distribution of healthy individuals and patients with LADA, type 1 and 2 DM by genotypes with C1858T of *PTPN22* gene - $\chi^2 = 47.063$, $p = 0.000$.

Investigation of distribution of C1858T genotypes of *PTPN22* gene has shown the significant homozygotes association of this polymorphism with LADA, type 1 and 2 DM. It should be noted, that homozygous carriers of this polymorphism occur significantly more often among patient with LADA than among the ones with 1 and 2 type DM. Significant distinctions in genotypes frequencies between the patients with type 1 and 2 DM was not revealed (Table 7).

Thus, the investigation of association of single nucleotide of C1858T polymorphism of *PTPN22* gene has shown its evident association with LADA, type 1 and 2 DM.

The obtained data overlap with existing works on this polymorphism investigation in populations of Ukraine, the USA, Poland, Finland, Sweden, Norway and others [67-69]. For example, in Sweden populations [69] the association of this polymorphism with all DM clinical forms was shown: frequencies of carriage of mutant homozygote T/T in patients with type 1, 2 DM, LADA and in control were 0.3, 3.8, 2.8 and 4.3% accordingly. The most expressed association of this polymorphism was observed with LADA. The investigation results allow to assume that development of such DM form as LADA is caused more by changes in the genes, controlling normal immunological homeostasis, and that determines the features of course of this disease form even in all genes of HLA system absence, which are necessary for type 1 DM development.

Additionally, we studied the distribution of polymorphism of 49A/G of *CTLA4* gene, which causes the immune disorders, in patients with different clinical variants of DM.

The results obtained are presented in Table 8.

These results are concordant with the data about 49A/G of *CTLA4* gene polymorphism association with type 1 DM in different populations of the world [240]. To determine the frequency of this polymorphism in different clinical variants of DM course in Kharkov population, we carried out the comparative analysis of frequencies of 49A/G *CTLA4* gene polymorphism among the patients with type 1, 2 DM and LADA.

Table 8. The frequencies of genotypes with 49A/G *CTLA4* gene polymorphism in DM patients and healthy Kharkov citizens

Index	Control, N = 75		Patients		χ^2	Significance of differences (p)	OR (95% CI)
	N	%	n	%			
Type 1 DM, N = 64							
Genotype: A/A	29	38.67	12	18.75	5.644	0.014	0.37 (0.31-1.41)

G/G	12	16.00	46	42.20	12.943	0.000	3.83 (0.87-3.89)

The genotypes distribution analysis among all compared groups has shown the reliable difference in patients with LADA, type 1 and 2 DM in comparison with the healthy Kharkov citizens ($\chi^2 = 17.853$; $df = 6$, $p = 0.001$).

There was shown a significant association of G/G mutant homozygotes with type 1, 2 DM and LADA ($OR_{type\ 1\ DM} = 5.61$; $OR_{type\ 2\ DM} = 4.27$; $OR_{LADA} = 7.30$). It should also be noted, that homozygous carriers of 49A/G of *CTLA4* gene polymorphism appeared more often among the patients with LADA than among the patients with type 2 DM (Table 9).

No significant distinctions in the genotypes frequencies in patients with type 1 and 2 DM are revealed. The comparative analysis results of E23K polymorphism of *KCNJ11* gene distribution, participating in development of insulin deficiency and determining the type 2 DM susceptibility, among the patients with LADA, type 1 and 2 DM are given in Table 10.

Table 9. Distinctions in frequencies of genotypes and polymorphism alleles of 49A/G *CTLA4* gene in DM patients

Compared groups	Index	χ^2	Significance of differences (p)

	E/K	1.243	0.265
	K/K	0.088	0.767

It should also be noted, that the homozygous carriers of E23K of *KCNJ11* gene mutation appear more often among the patients with LADA, when comparing to the patients with type 1 and 2 DM (Table 10). There are no significant differences in genotypes frequency among the patients with type 1, 2 DM and LADA (Table 11).

Figure 4 shows distribution of polymorphisms 49A/G of *CTLA4* and C1858T of *PTPN22* genes in patients with different clinical variants of DM course.

The significant distinctions of distribution of genotypes with 49A/G of *CTLA4* and C1858T of *PTPN22* genes ($\chi^2 = 23.485$; $df = 16$; $p = 0.000$) among the compared groups of patients were shown. The pair-wise comparison of DM clinical variants shown the significant distinctions between the patients with LADA and type 2 DM ($\chi^2 = 10.622$; $df = 8$; $p = 0.031$). There was found no significant distinctions in this polymorphisms between the patients with LADA and type 1 DM; and type 1 and 2 DM ($\chi^2 = 4.098$; $df = 8$; $p = 0.393$; $\chi^2 = 3.970$; $df = 8$; $p = 0.410$, accordingly). The frequency of carriage of homozygote GG/TT genotypes in the patients with LADA was significantly higher than such in the patients with type 2 DM (8.30 and 1.60%, accordingly, $\chi^2 = 4.425$, $p = 0.035$).

Figure 4. Distribution of polymorphisms 49A/G of *CTLA4* and C1858T of *PTPN22* genes in patients with different clinical variants of DM course.

Figure 5. Distribution of 49A/G polymorphisms of *CTLA4* gene and E23K of *KCNJ11* gene in patients with different clinical variants of DM course.

Distribution of patients by carriage of polymorphisms of 49A/G of *CTLA4* gene and E23K of *KCNJ11* gene is presented on Figure 5.

The significant distinctions in distribution of genotypes with 49A/G of *CTLA4* gene and E23K of *KCNJ11* gene ($\chi^2 = 19.978$; $df = 16$; $p = 0.000$) among the compared groups of patients were shown. The pair-wise comparison of DM clinical variants shown the significant distinctions between the patients with LADA and type 1 DM ($\chi^2 = 12.065$; $df = 8$; $p = 0.017$); between the patients with LADA and type 2 DM ($\chi^2 = 10.976$; $df = 8$; $p = 0.027$). The significant distinctions in this polymorphisms between the patients with type 1 and 2 DM were not found ($\chi^2 = 7.859$; $df = 8$; $p = 0.097$). The frequency of carriage of homozygote GG/KK genotypes in patients with LADA was significantly higher than the one in the patients with type 2 DM (21.54 and 8.86%, accordingly, $\chi^2 = 3.840$, $p = 0.050$).

Distribution of patients by carriage of polymorphisms of C1858T of *PTPN22* gene and E23K of *KCNJ11* gene is presented on Figure 6.

The significant distinctions in genotypes distribution with C1858T of *PTPN22* gene and E23K of *KCNJ11* gene ($\chi^2 = 11.146$; $df = 16$; $p = 0.025$) among the compared groups of patients were shown. The pair-wise comparison of DM clinical variants shown the significant distinctions between the patients with LADA and type 2 DM ($\chi^2 = 5.233$; $df = 8$; $p = 0.264$). The significant distinctions in this polymorphisms between the patients with LADA and type 1 DM, also between the patients with type 1 and 2 DM were not found ($\chi^2 = 5.928$; $df = 8$; $p = 0.205$; $\chi^2 = 6.303$; $df = 8$; $p = 0.178$, accordingly).

Figure 6. Distribution of polymorphisms of C1858T of *PTPN22* gene and E23K of *KCNJ11* gene in patients with different clinical variants of DM course.

Distribution of patients by carriage of polymorphisms of 49A/G of *CTLA4* gene, C1858T of *PTPN22* gene and E23K of *KCNJ11* gene is presented on Figure 7.

The significant distinctions in distribution of the genotypes with C1858T of *PTPN22* gene and 49A/G of *CTLA4* gene, and E23K of *KCNJ11* gene ($\chi^2 = 56.923$; $df = 46$; $p = 0.000$) among the compared groups of patients were shown. The pair-wise comparison of DM clinical variants shown the significant distinctions between all investigated groups: the patients with LADA and type 1 DM ($\chi^2 = 23.978$; $df = 23$; $p = 0.000$); the patients with LADA and type 2 DM ($\chi^2 = 19.341$; $df = 23$; $p = 0.000$); the patients with type 1 and type 2 DM ($\chi^2 = 21.071$; $df = 20$; $p = 0.000$); that indicates the genetic independence of all these clinical DM forms.

However, if the genetic independence of type 1 and 2 DM is well-proven, the genes of susceptibility to these disease types are selected, a question about LADA genetic determination and reasons for its occurrence remain open to date. It is assumed for today, that LADA is the variant of type 1 DM course [81]. The molecular-genetic research, conducted by us, shown LADA genetic independence, confirming the results of genetic [51] analysis, obtained before.

Figure 7. Distribution of polymorphisms of 49A/G of *CTLA4* gene, C1858T of *PTPN22* gene and E23K of *KCNJ11* gene in patients with different clinical variants of DM course.

Absence of significant distinctions among the investigated single gene polymorphisms in the patients with type 1 and 2 DM completely corresponds to the genetic analysis results, which indicated the presence of 59% common genes in type 1 and 2 DM determination [41]. Taking into account the fact that type 1 and 2 DM are polygenetic diseases, not only the genes, which caused one or another DM type development, the genes combination is significant too. Selection tension against type 1 DM reduction, caused by the insulin therapy introduction, and positive direction of genes of susceptibility to type 2 DM selection resulted not only in increase of the genes of susceptibility to type 1 and 2 DM in population, but also in their combination variants increase. It leads, in particular, to growth of such genetically independent DM form as LADA and increases its prevalence among the DM patients.

Thus, the conducted research showed the selection role in changing of prevalence of type 1 and 2 DM in population and in evolution and in origin of DM clinical forms.

DISCUSSION

In this work the peculiarities of different DM types selection, which appear in different ontogenetic periods and differ in morbidity and genetic determination, were studied. Thus, if type 1 DM, without an adequate insulin therapy, results in fatal outcome and, to some extent, can be partly associated with the factors, regulating the population amount, type 2 DM, vice versa, promoted the increase of survival rate of carriers of this trait in the past historical periods with food deficiency. According to J.V. Neel conception, the special genes (thrifty gene), which allowed a man to use effectively the limited food resources, results in obesity and type 2 DM development in the conditions of food abundance [28].

The conducted research showed, that selection in favour of diseases, which commonly start in a post-reproductive period, to which type 2 DM belongs, exists till the present time. The reasons, determining the positive direction of type 2 DM selection, remain unknown till today and, probably, can be of interest for further researches. The selection positive direction was accompanied by significant growth of their prevalence in population over a generation.

Peculiarities of type 1 DM selection were influenced by the modern medicine, which succeeded in compensating the disease with the insulin therapy. This enabled a patient to survive and produce genotype. Type 1 DM in the “pre-insulin period” belonged to the sub-lethal traits. Its manifestation usually occurs in the pre-pubertal or pubertal period, and then during half a year – a year such patients died from the hyperglycemic coma. The insulin therapy allowed to correct the disease course significantly, however, the negative consequences cannot be completely neutralized till today, that changed type 1 DM from sub-lethal trait into the trait of reduced adaptability. The peculiarities of clinical course of type 1 DM result in lower genotype survival rate that determines the low relative adaptability of disease and, accordingly, the negative selection direction.

The insulin therapy introduction in 50th years of 20th century into the common health care practice has led to decrease of selection tension against type 1 DM and increase of the population prevalence of this type of disease. Growth of type 1 DM prevalence proceeded up to 1995, approximately for two generations (fifty years). After 1995 the rapid growth of type 1 DM prevalence has stopped, apparently, the existent selection against type 1 DM tension played a certain role in it. Consequence of the ongoing processes is not only increased prevalence of

type 1 DM in population, but also the increased clinical DM heterogeneity. Increase in frequency of genes of susceptibility to type 1 DM in population, caused by selection tension reduction, was not only the basis for increase of population prevalence of this disease type, but also promoted probability of genes occurrence in proband, determining development of both DM types. The result of this phenomenon could be a formation and growth of prevalence in DM structure of such clinical form of disease as LADA [51], which heritability is described by the polygene threshold model parameters. In its inheritance the essential role belongs to the genetic factors (59.2%), there are nonlinear genetic intraloci and interallelic ($GD = 1.2\%$) interactions and influence of number of genes with evident effect in determination of this form of disease is possible. Although LADA is an independent DM genetic form, but, according to Ch. Smith model testing, there is approximately the same amount of common genes of susceptibility to type 1 and 2 DM (65.3 and 66.1%, accordingly) in its genetic control system.

Conducted researches of polymorphisms of C1858T of *PTPN22* gene and 49A/G of *CTLA4* gene, associated with type 1 DM in patients with different DM clinical forms, show that those polymorphisms are associated with type 2 DM and with LADA. Analogical data on associations of this polymorphisms with type 1 and 2 DM and LADA were obtained also in other populations in different countries of the world [67-72]. It should be noted, that the insulin therapy introduction into the common health care practice for correction of type 1 DM course was observed in all countries of the earth. And such disease compensation allowed to reduce considerably the selection tension against this type of DM in all countries. It increased the frequencies of genes of susceptibility to type 1 DM in all populations. Therefore, the association of polymorphism of C1858T of *PTPN22* gene and type 1 DM is not local, but observed in different countries. The model, presented before, of type 1 DM inheritance [41] indicated the linked factors, determining the hereditary susceptibility to this type of disease (high values of epistatic components). It is presently known, that antigens of the HLA system are the major contributors to type 1 DM development [42]. The HLA system antigens are codominantly inherited and are linked factors [82]. Other genes of susceptibility to type 1 DM, such as *CTLA4*, *PTPN22*, *IL2RA*, *IFIH1*, *IL2*, *PTPN2* and *KIAA0350*, are localized on different chromosomes [42]. Taking into account that these genes are linked considerably less, than antigens of the HLA system, it is logically to assume that *CTLA4*, *PTPN22*, *IL2RA*, *IFIH1*, *IL2*, *PTPN2* and *KIAA0350* genes can form different combinations with the genes of susceptibility to type 2 DM in a proband. From this point of view, it is understandable that LADA patients more frequently than the ones with type 1 DM have such gene polymorphisms as C1858T *PTPN22* and 49A/G *CTLA4* genes. The observed phenomenon corresponds to ideas of numerous authors, that LADA has an autoimmune nature, but differs from type 1 DM by type of insulin dependence and by distribution of susceptibility to DM alleles [49]. Frequency of C1858T of *PTPN22* gene and 49A/G of *CTLA4* gene polymorphisms in type 2 DM is considerably less than in LADA and is analogical to the one in type 1 disease, although carriage of this polymorphisms is not significant in pathogenesis of type 2 DM. It can be explained by selection tension reduction against type 1 DM, caused by the insulin therapy implementation, accompanied by increase of population genes frequency, causing the type 1 DM development. It can logically explain the fact of association of C1858T of *PTPN22* and 49A/G of *CTLA4* genes polymorphisms with type 2 disease, because the selection tension reduction promoted the occurrence probability of the genes of susceptibility to type 1 DM in patients with type 2 DM. However, the presence of one or another genes polymorphism, determining the immune response disorders in patients with type 2 DM, does not cause any autoimmune aggression

against the pancreatic islet cells, as the latter is caused by a combined effect of multiple mutations, causing immune response disorder.

Because the genetic control system LADA, in according the heredity model, has a bigger part of common genes with type 2 DM, it was logical to study an association of LADA, type 1 and 2 DM with polymorphism of E23K of *KCNJ11* gene, which determines the development of insulin insufficiency in a proband which is a gene, taking part in the susceptibility to type 2 DM forming [42]. The obtained results were analogical to our data about the association of polymorphisms of C1858T of *PTPN22* gene and 49A/G *CTLA4* gene and DM. The significant association of this mutation with all clinical variants of DM course (Table 10) was also shown. Thus, the conducted molecular-genetic researches confirmed positions of LADA and type 1 and 2 DM inheritance models about existence of common genes in their genetic control systems.

The distribution of the patients with different clinical variants of DM course by the polymorphisms of C1858T of *PTPN22*, 49A/G of *CTLA4* and E23K of *KCNJ11* genes shown the significant distinctions ($\chi^2 = 56.923$; $df = 46$; $p = 0.000$) in the distribution of patients with different clinical variants of disease course by the genotypes, which were investigated. The pair-wise comparison of patients groups revealed the significance of distribution of patients by the carriage of polymorphisms, which were studied among all investigated groups, that proves the genetic independence of all these DM forms. Conducted molecular-genetic research showed LADA genetic independence, confirming our genetic analysis results [51]. In addition it should be noted, that larger, than among the patients with type 1 and 2 DM, number of homozygote carriers of all three mutant alleles is characteristic for LADA. The obtained data confirm Hamaguchi assumption, that LADA has an autoimmune nature, but differs from type 1 DM by types of the insulin dependence and distribution of alleles, susceptible to DM [49]. And exactly the high frequency of mutant homozygote carriers of immune response genes among the patients with LADA, and only partial availability of the HLA genes system in them, which is forming the susceptibility to type 1 DM, determine late development of this DM form and its less severe course. The high percentage of homozygotic carriers of mutations, forming susceptibility to type 1 and 2 DM, is a bright confirmation of assumption about the selection influence on evolution of DM clinical forms. Exactly the high percent of homozygotic carriage of polymorphic alleles, simultaneously by all three investigated positions in LADA patients, illustrates the position that this form of DM occurs as a result of selection action because of frequencies increase of the genes of susceptibility to both type 1 and 2 DM in population.

CONCLUSION

Thus, natural selection has defined the prevalence dynamics and influences formation of the polygenic diseases heterogeneity, to which DM belongs.

Chapter 14

GENETIC DRIFT AMONG NATIVE PEOPLE FROM SOUTH AMERICAN GRAN CHACO REGION AFFECTS INTERLEUKIN 1 RECEPTOR ANTAGONIST VARIATION

Cecilia Inés Catanesi* and Laura Angela Glesmann

Laboratory of Genetic Diversity, IMBICE, La Plata, Argentina

ABSTRACT

Genetic variation is generally responsible for ethnic differences in certain diseases, including inflammatory processes. The antagonist of cytokine IL-1, IL-1Ra, has been widely studied among Caucasian and African populations for genetic polymorphisms, and interethnic differences have been documented. However, the variation and genotype distribution of polymorphisms from these genes among South American Amerindians are thus far unknown. We present the results for a VNTR located in the IL-1Ra second intron, in a sample of 169 individuals belonging to 5 Native American populations from Argentina and Paraguay, identified as native according to their self designation, and their geographic location. We also compare this data with the results obtained from a sample of non-native Argentinian people. Among the five known alleles of the VNTR, we found only two (alleles 1 and 2) in the native populations from Gran Chaco, and heterozygosity was 19%. The allele 2 which is considered proinflammatory (IL-1Ra * 2) has been found in homozygosity at a considerable frequency among native individuals. However, the association of this allele with inflammatory disease previously demonstrated for other populations of the world, might not be acting in the same way for native people, probably due to local adaptation. This would indicate that the allele 2 will probably not have a negative influence on individuals of native origin who have homozygous genotype 2-2. On the contrary, few records on inflammatory disease are available for the native people.

It seems that the increment on allele 2 is not related to any adaptive process but to genetic drift, that changes randomly the allele frequencies of different genetic regions along the genome. The effect of genetic drift has already been demonstrated with genetic markers located in autosomes, X and Y chromosomes. These results indicate that we must be very cautious when studying populations that passed a process of genetic drift, which can

* Corresponding Author's Email: ccatanesi@imbice.gov.ar.

become a confounding factor in epidemiological studies. This information will contribute to a future understanding of the association of this polymorphism with disease, and its incidence in different ethnic groups.

TEXT

The native human populations inhabiting the American territory have arrived to the continent through different migratory events, and have been involved in social and cultural interactions with other human groups. This exchange can be partially reflected in their current genetic structure. However, other processes than genetic flow have played an important role in the microevolutionary change of these populations, and genetic drift might be, even nowadays, one of the most important processes acting on them.

Figure 1. Geographic location of the phytogeographic Gran Chaco region.

Before the arrival of the European colonizers, the Gran Chaco region possessed a rich cultural and linguistic diversity. But the initial contact between Native Americans and Europeans five hundred years ago, initiated a dramatic reduction of the native populations, as happened in other parts of the American continent (Martínez Sarasola 2004). Many groups

were completely wiped out, while others have introduced some genetic admixture from non-native groups (Mulligan et al. 2004) giving rise through the centuries to the current Latin American populations, which share three main ancestral origins: Native American, European, and African (Salzano & Bortolini 2002, Rondón et al. 2008). In this chapter we present the analysis of some extant native groups inhabiting the South American Gran Chaco region, and the genetic drift process that can be found through genetic analysis. Information on these populations is not always concordant with the conclusions on their origin and history (Torroni et al. 1993, Horai et al. 1993, Zago et al. 1995), in part due to the genetic drift process, which generates a strong differentiation among tribes.

The Gran Chaco is a plain, very wide phytogeographic region of approximately 100.000 km², which includes part of Bolivia, Paraguay, and northeast of Argentina (Figure 1). About 5.000 years ago it was colonized by several nomadic native groups of hunting, fishing and gathering habits: Abipon, Mocoví, Qom, Mbya, and Pilagá belonging to Guaycurú linguistic group, Wichí, Chorote, and Chulupí of the Mataguayo linguistic family, and the Lule-Vilela group in the western part, corresponding to current Argentinian territory. In the northeast, the Ayoreo and Lengua, live in the region that belongs to Paraguay. These ethnic groups did not practice written language, therefore the historical record begins with the arrival of Spanish colonizers, and before that moment, information can be obtained only from oral transmitted tales (Martínez-Sarasola 2004; Tissera, 2008). These native groups show an important diversity of spoken languages as a result of complex interactions and interchanges (Jurado Medina et al. 2014).

BACKGROUND

Molecular biology offers a wide variety of coding and non coding (neutral) DNA markers for analyzing the diversity among individuals of a population, and among populations of a region. There is a background of information on DNA markers for Gran Chaco populations including several SNPs (single nucleotide polymorphisms), STRs (short tandem repeats, also called microsatellites), and insertions-deletions. SNPs are small changes in the DNA sequence affecting only one nucleotide. Usually, SNP mutation rates are moderate to low. STRs are short sequences tandemly repeated, they are highly variable and highly informative for studying genetic diversity and evolutionary processes. Insertion-deletion markers are sequences that are either present or absent, and can extend from only one or few nucleotides to several hundreds of them. An important amount of information has been obtained from non coding markers in Y chromosome, mitochondrial DNA, autosomes and X chromosome, while much fewer information is available from coding regions, such as blood antigens and HLA genes (Goicoechea et al. 2001, Dejean et al. 2004).

UNIPARENTAL Y CHROMOSOME VARIABILITY

Male specific region of Y chromosome has been widely studied throughout the world, allowing to disentangle the genetic structure of different populations. The diversity of Gran

Chaco native people has been analyzed through uniparentally inherited markers localized in Y chromosome, SNP and STR polymorphisms.

For the native populations of Gran Chaco, the search of autochthonous Q1a3a haplogroup has been firstly focused among different Chaco groups to determine either a native or a non-native origin of this chromosome. This haplogroup is determined by M3 SNP marker. Among those considered native, a set of STR markers has been usually genotyped to determine the diversity of each analyzed group.

An analysis on three different ethnic groups, Pilaga, Wichí, and Toba on SNP and STR markers showed genetic drift as a powerful evolutionary force for these seasonal hunters living in small bands (Demarchi and Mitchell 2004). The Native American-specific M3 marker was carried by 76.9% of the individuals, with a moderately high intergroup variation based on Y-chromosome STRs (10.7%).

In this way, two populations of Wichí origin living in Formosa province, 70 kilometers away from each other, were analyzed by Ramallo et al. (2009), showing a frequency of the Q1a3a haplogroup of 72,7% and 81,6%, and a rich lineage variability regionally distributed. Allelic variation was also non coincident. Their nomadic way of life and their habit to live in small groups has been clearly a strong force driving to genetic drift. Moreover, the Wichí people show a distribution of partialities called “Wichí ethnic complex” with certain linguistic differences (Braunstein 2006, Ramallo et al. 2009).

However, a small sample belonging to another ethnic group, did not show such influence. The Mocoví people living south to Gran Chaco, in Santa Fe province, were also analyzed for Y markers including two SNPs (M3 and M346) and ten STRs (Glesmann et al. 2011). The M3-T transition was present in 52% of the individuals, and STR haplotype diversity was 99.69%. In this case, the Mocoví Y-chromosomes still retain an interesting variability, with some of the M3-T haplotypes not found in other Amerindian groups. This considerable amount of haplotype variability is likely to be originary from this population.

X CHROMOSOME VARIABILITY

Due to its particular mode of inheritance, and its lower recombination rate compared to autosomes, the patterns of genetic variation of different types of markers specifically located in the X chromosome can result highly informative for population studies. Indeed, its special characteristics give a chance for analyzing genetic variability from a different point of view (Bourgeois et al. 2009, Ribeiro Rodrigues et al. 2009, 2011).

A study on X chromosome variation was performed including five Chaco ethnic groups: from Argentina, Wichí and Chorote from Salta province, and Mocoví from Santa Fe; from Paraguay: Lengua and Ayoreo (Catanesi et al. 2007). This analysis showed significant differences among these populations, with high F_{st} and R_{st} values, probably due to the drift process. The differentiation was related to the geographic location of populations, grouping those from Salta together, and those from Paraguay together, with Mocoví resulting separated from the rest (Catanesi et al. 2007).

A more recent study included another Wichí population living in a region called “Impenetrable” due to its hard climatic conditions and dense vegetation, in the Chaco province, and a Mocoví population (the same that was analyzed for Y chromosome) living in the south

of Gran Chaco (Glesmann et al. 2013). A high proportion of homozygotes and a marked linkage disequilibrium was found especially in Wichí, with differences in modal alleles and frequencies between both populations. On the other hand, a higher proportion of variation was observed in Mocoví. It has been reported that the Mocoví people belonging to the studied population are currently taking part of the neighbor non-native society through work and education.

This social integration might be responsible for a cultural change among Mocoví (Franceschi and Dasso, 2010). Although the genetic flow between Mocoví and non-natives might be occurring (Citro, 2006), a more important process of genetic drift may be reflected in the X chromosome variation reported, especially among Wichí. The Wichí people from Chaco province not only live isolated from other native and non-native groups, but also display an irregular distribution in small bands along the territory. Their geographic isolation and the extreme environmental conditions may be considered as the major factors contributing to the population differentiation (Glesmann et al. 2013).

UNIPARENTAL MITOCHONDRIAL VARIABILITY

Native Americans share five different maternally inherited mitochondrial DNA haplogroups: A, B, C, D, and X (Schurr et al. 1990, Torroni et al. 1993, Santos et al. 1996), which are present in different proportions depending on the demographic background of each population (Bailliet et al. 2004, Avena et al. 2012, Wang et al., 2008, Pauro et al. 2010, Yang et al. 2010, Motti et al. 2013).

An unbalanced proportion of male and female native uniparental lineages has been clearly described, as a consequence of mixed marriages of European males with native women through the last 5 centuries, thus making maternal haplogroups of native origin to widespread in different regions (García and Demarchi, 2006, 2009, Pauro et al. 2010, Yang et al. 2010).

Interestingly, a loss of mitochondrial variability has been described for certain Gran Chaco communities, including Wichí from Chaco province and Ayoreo from Paraguay. The random action of genetic drift or a bottleneck effect has been proposed as responsible for this reduction (Demarchi et al. 2001, Demarchi and Mitchell 2004).

AUTOSOME NON CODING VARIATION

Studying different genomic compartments has contributed to the understanding of the evolutionary processes occurring among South American Gran Chaco native populations. Different autosomal STR markers have shown in general a drop in the number of alleles and, consequently, an excess in the proportion of homozygote individuals. Variation in modal alleles for each native population, and a drastic reduction in allele number were found, particularly among Wichí (Tourret et al. 2000; Catanesi et al. 2001). As a consequence of genetic drift, a relatively poor correlation with geographic location of the tribes was more notable when analyzing autosomal variation (Zago et al. 1996; Tourret et al. 2000; Catanesi et al. 2001) than X chromosome variation (Catanesi et al. 2007).

AUTOSOME CODING VARIATION IN THE INTERLEUKINE 1 RECEPTOR ANTAGONIST

Coding genetic variation is generally responsible for ethnic differences in certain diseases. Natural selection changes allele frequencies according to environmental conditions, thus modifying the diversity of a population under selection (Hedrick 2000). Information on coding regions is scarce for native populations from Gran Chaco region, but the HLA region has been reported to present a low variability of dinucleotide STRs for three Chaco tribes: Wichí, Chorote, and Toba (Dejean et al. 2004), and metabolic genes have also been studied (Bailliet et al. 2007).

The inflammatory processes can be more prevalent among individuals who belong to a certain ethnic group, thus needing a specific medical treatment. Interleukin-1 (IL-1) is a cytokine secreted by macrophages and other cell types, playing an important role in the inflammatory response of virtually all cells and organs, as a major pathogenic mediator inducing pain (Dinarello et al., 2012; Gabay et al., 2010; Sims and Smith, 2010, Garlanda et al. 2013). The IL-1 gene family comprises several genes including three closely related IL-1A, IL-1B, and IL-1Ra encoding respectively two proinflammatory cytokines IL-1 α , IL-1 β , and their natural antagonist, the IL-1 receptor antagonist (IL-1Ra). The latter blocks IL-1 action by competing for its receptor (Dinarello 2009). The gene coding IL-1Ra maps the long arm of human chromosome 2 (band q14-21) (Steinkasserer et al. 1993, Grover et al. 2006). This gene presents a polymorphic VNTR in intron 2, with an 86 base pair repeated motif responsible for differences in the levels of expression of the receptor, which is reportedly associated with autoimmune diseases, ischemic stroke, and other pathologies (Worrall et al. 2007). The VNTR presents 5 allelic variants corresponding to 2, 3, 4, 5, and 6 copies of the 86 bp repeat (Tarlow et al. 1993, Grover et al. 2006). Three potential protein binding sites are located nearby this polymorphism, therefore the number of repeats may influence the level of gene transcription and posterior translation to a protein product.

Studies on North American U.S. population proposed the association of the allele IL-1Ra*2 of this VNTR with chronic inflammatory processes and pain (Joos et al. 2001, Foster et al. 2004), and this allele has also been associated as a risk factor for various autoimmune diseases (Rider et al. 2000, You et al. 2007, Havemose-Poulsen et al. 2007).

Since genetic diversity at the immune system is primarily important for human population's survival, the variation of this polymorphism in a group of native people inhabiting the South American Gran Chaco was explored.

A sample of 169 Amerindians from the Gran Chaco region -including Argentina and Paraguay, and a sample of 107 non-Amerindian Argentineans mainly of European ancestry (from Misiones and Buenos Aires provinces, Argentina), were analyzed. The Amerindians, identified as native according to their self designation, and their geographic location, comprised individuals belonging to five native groups from Gran Chaco: Lengua (from Paraguay, n = 36), Ayoreo (from Paraguay, n = 41), Chorote (from Santa Victoria Este, Salta province, Argentina, n = 20), Wichí (also from Santa Victoria Este, n = 39), and Mocoví (from Colonia Dolores, Santa Fe province, Argentina, n = 33). A small sample of 26 non-Amerindian Argentinians of full Japanese ancestry was also genotyped, however this group was not polymorphic for this VNTR, showing only homozygote individuals for allele 4, probably due to the small number of individuals analyzed, therefore this sample was not included in the comparative analysis.

The VNTR was amplified using the primers Fw: CTCAGCAACACTCCTAT, and Rv: TCCTGGTCTGCAGGTAA, in a MPI-Evo02 Thermocycler (La Plata, Argentina). Cycling conditions included 36 cycles of 94° 40 sec., 57° 1 min., and 72° 1 min., with an initial denaturation of 94° 2 min., and a final extension of 72° 5 min. Alleles were defined in 2% agarose electrophoresis, as in Foster et al. (2004). After post-gel DNA staining with GelGreen™ (Biotium, Hayward, CA), the electrophoretic bands were visualized in an image analyzer GelDocXR (Biorad, USA).

Allele frequencies, gene diversity, exact test of Hardy-Weinberg equilibrium, molecular variance (AMOVA), and pairwise genetic distances measured as Wright index F_{st} and R_{st} , were analyzed with Arlequin v. 3.5 (Excoffier et al. 2010). The F_{st} index estimates the amount of genetic differentiation between populations, by comparing total heterozygosity (five populations together) to each population heterozygosity. Genetic distances were represented using a matrix of distance MDS (multi dimensional scaling) with the program NTSYS 2.1 (Exeter) using R_{st} Slatkin's estimation from allele frequencies.

We found three out of the five known alleles of this VNTR (Table 1). The allele 2 was more frequent among the native people than in European and North American populations, and the allele 5 was found only in non-native European ancestry people.

Table 1. Sample size and genotype frequencies observed for IL1-Ra VNTR. Alleles are named by the number of repeats

Population	Sample size	Genotype Frequencies					
		2/2	2/4	2/5	4/4	4/5	5/5
Lengua	36	0.111	0.278	-	0.611	-	-
Ayoreo	41	0.024	0.195	-	0.780	-	-
Chorote	20	0.2	0.1	-	0.7	-	-
Wichí	39	0.205	0.154	-	0.641	-	-
Mocoví	33	0.061	0.182	-	0.757	-	-
Buenos Aires	104	0.038	0.010	-	0.875	0.019	0.058
Misiones	77	0.065	0.078	0.013	0.740	0.013	0.091
Japanese	26	-	-	-	1	-	-

Total native heterozygosity was 19%, while non-native people showed a much lower value, 2,5%. Genotypic distribution did not fit Hardy-Weinberg equilibrium among Chorote and Wichí Amerindians (Chorote: observed heterozygosity = 0.100, expected heterozygosity = 0.385, $P = 0.00278 \pm 0.00005$; Wichí: observed heterozygosity = 0.154, expected heterozygosity = 0.410, $P = 0.00019 \pm 0.00001$). It is noteworthy that the VNTR did not fit populational equilibrium in two cases, mostly due to the presence of higher frequencies of homozygotes for allele 2 than expected (Table 2). The genotyping of this marker was rechecked for those homozygotes, and such genotypes were confirmed.

Pairwise F_{st} analysis showed significant values for non-native (Buenos Aires + Misiones) compared to native populations, except for Ayoreo, and also between Wichí and Ayoreo (Table 3, data below diagonal). On the other hand, for pairwise R_{st} estimations non significant values were observed (Table 3, data above diagonal). R_{st} value between Wichí and non-native gave a limit probability of $P = 0,5$, showing a tendency to differentiation.

Table 2. Allele frequencies for the five Amerindian ethnic groups (frequencies +/-S.D.)

Allele	Mocoví	Lengua	Ayoreo	Chorote	Wichí
2	0.152+/-0.044	0.250+/-0.051	0.122+/-0.036	0.250+/-0.069	0,282+/-0,051
4	0.848+/-0.044	0.750+/-0.051	0.878+/-0.036	0.750+/-0.069	0,718+/-0,051

Table 3. Population pairwise Fst and Rst values below and above the diagonal, respectively. Significant results are in bold ($\alpha = 0.05$)

Population pairwise Rst							
Population pairwise Fst		Non-native	Wichí	Chorote	Ayoreo	Lengua	Mocoví
	Non-native		0.01555	-0.00278	-0.00242	0.00310	-0.00898
	Wichí	0.12312		-0.01662	0.06532	-0.01088	0.03460
	Chorote	0.09339	-0.01662		0.04015	-0.01983	0.01135
	Ayoreo	0.00760	0.06532	0.04015		0.04112	-0.01008
	Lengua	0.09222	-0.01088	-0.01983	0.04112		0.01524
	Mocoví	0.01772	0.03460	0.01135	-0.01008	0.01524	

An analysis of molecular variance (AMOVA) (Table 4) showed a significant 3.77% differentiation between native and non-native people ($P = 0.03773$).

Figure 2. Multidimensional scaling (MDS) obtained from Rst distance matrix (Stress value = 0.0000). Non-native sample includes populations from Buenos Aires and Misiones.

Multidimensional map obtained from Rst distances (Figure 2) did not show any clustering, but the distribution of native populations showed certain agreement with their geographic distribution, with Mocoví (the population in a southernmost location) positioned distant from

all other populations, Lengua near Ayoreo, and Chorote near Wichí. It is interesting to remark the close position of Wichí and non-native people, consistent with a migrational process. However, F_{st} values suggest the migrational process is more likely occurring among these native populations.

Table 4. AMOVA Analysis (distance method: F_{st}). Samples for testing genetic structure were grouped as native and non-native populations $\alpha = 0.05$

	Sum of squared	Variance components	Percentage of variation
Among groups	2,143	0.00565	3.77
Among populations within groups	1.443	0.00329	2.20
Within populations	76.869	0.14079	94.03
Total	80.455	0.14973	100

DISCUSSION

The existence of an enormous drift in American native people, acting on small subpopulations and generating variation from one population to another, has been emphasized. The stochastic accumulation of differences through the time often increases differences among populations, while intrapopulation variation decreases enormously (Cavalli-Sforza et al. 1996).

Our results on a VNTR polymorphism within a coding region might be interpreted in different ways. On the one hand, natural selection might be acting on these populations favouring proinflammatory allele 2 in order to increase a particular inflammatory-immune pathway, since many individuals belonging to native Gran Chaco populations are still living under strict environmental conditions. However, it is more likely to interpret these results as the effect of finite population size making variability to be lost rapidly.

The decrease in heterozygosity of each population compared to the diversity of the pooled native sample taken together, and the low variability observed within populations are consistent with a genetic drift process (Holsinger 2015).

When populations are isolated from one another, as it happens especially with Wichí people, they will tend to diverge from one another as a result of genetic drift. This tendency operates much faster in populations with few individuals, driving them to divergence (Hedrick 2000).

The influence of genetic drift could be detrimental to perform association genetic studies for specific diseases, because case-control and/or cohort studies might drive to erroneous conclusions when comparing populations which are substructured and in disagreement with Hardy-Weinberg equilibrium (Acosta et al. 2012).

However, the association of this allele with inflammatory disease previously demonstrated for other populations of the world, might not be acting in the same way for native people, probably due to local adaptation. This would indicate that the allele 2 probably does not influence negatively on individuals of native origin who have homozygous genotype 2-2. On the contrary, few records on inflammatory disease are available for the native people (Trujillo Miriam, personal communication). It seems that the increment on allele 2 is not related to any

adaptive process but to genetic drift, that changes randomly the allele frequencies of different genetic regions along the genome. The effect of genetic drift has already been demonstrated with genetic markers located in autosomes, X and Y chromosomes (see above).

These results indicate that we must be very cautious when studying populations that passed through a process of genetic drift, which can become a confounding factor not only in evolutionary studies, but in epidemiological studies. In the first case, it could be considered as a positive selection effect; in the second one, the existence of a genetic association with certain phenotype could be falsely interpreted (Solovieva et al. 2004).

This information will contribute to a future understanding of the association of this polymorphism with disease, and its incidence in different ethnic groups.

ABSTRACT

Alternative splicing (AS) is a fundamental mechanism of gene expression regulation that extremely expands the coding potential of genomes and the cellular transcriptomic and proteomic diversity. This dynamic and finely-tuned machinery is particularly widespread in the nervous system and is critical for both neuronal development and functions. Alternative splicing defects, therefore, frequently underlie neurological disorders. In this chapter, we will focus on Parkinson's disease (PD), the second most common neurodegenerative disorder worldwide. We will provide a current overview on the impact of alternative splicing in PD by representing the multiple splicing transcripts produced from the major PD-linked genes and their regulation in PD states. Furthermore, we will review the studies describing global splicing expression changes revealed by whole-genome transcriptomic approaches. We will also summarize the current knowledge about the alternative splicing modulation in PD through non-coding RNAs (miRNA and lcnRNA) molecules. Assessing the role of alternative splicing on PD pathobiology may represent a central step toward an improved understanding of this complex disease.

1. INTRODUCTION

The DNA-RNA-protein flowchart has been for long time considered the central dogma of molecular biology. Further steps of regulation are continuously discovered, greatly expanding this simplistic framework and revealing the complex network that controls gene expression [1]. The multilayer biological processes that regulate gene expression include several RNA-based mechanisms, such as regulation of mRNA translation efficiency, stability and localization, miRNA-mediated silencing, long non-coding RNAs modulation, nonsense-mediated decay, polyadenylation site selection and RNA editing. Among these complex circuits, the most crucial layer is represented by alternative splicing (AS), a process whereby multiple mRNA transcripts and protein isoforms with different functional properties are created from a single gene [1]. More than 90% of multi-exon human genes undergo AS [2, 3]. The main site of AS events is represented by the central nervous system [4, 5].

Besides the physiological involvement of AS during development, many evidences suggest a significant contribution of this mechanism in human pathologies, and therefore its clinical relevance is growing exponentially. It is estimated that 50% of disease-causing mutations affect pre-mRNA splicing [1].

In this chapter, we will briefly introduce the AS process and its role in the pathophysiology of the nervous system. Then, we will focus on the current knowledge about its impact on Parkinson's disease (PD), the second most common neurodegenerative disorder worldwide. Hence, the multiple transcripts generated by the major PD-linked genes and their regulation during the disease will be reported.

During last years, the rapid advancement of biotechnologies has allowed to detect simultaneously, on large scale, gene-expression changes in various pathophysiological conditions. As a result, several studies on the global expression of splicing variants in PD have been performed and will be recapitulated at the end of the chapter. Finally, the current knowledge about the epigenetic modulation of AS mechanism in PD will be summarized. Deciphering the functional role of AS transcripts and encoded protein isoforms in PD may represent an essential step toward an improved understanding of this complex disease.

2. THE ALTERNATIVE SPLICING MACHINERY

In humans and other complex metazoans, the vast majority of genes are discontinuous, in other words, they contain mRNA-encoding regions, called exons, which are interrupted by non-coding segments, the introns. This split gene structure offers a fertile ground for AS regulation, by providing incredible opportunities to enhance the transcriptome and proteome repertoire without the need for expansion of the genome.

The AS process consists in the removal of introns from the pre-mRNA transcript and joining of the coding regions in various exon-exon combinations to form a mature mRNA, which is then polyadenylated, exported to cytoplasm, and translated into protein. Four main constitutive DNA sequence motifs enable the splicing process: the 5' (GU) and the 3' (AG) splice sites, the lariat branch point, and the polypyrimidine tract. In addition to the *core* splicing elements, other nucleotide sequences within exons (also known as ESEs, or exonic splicing enhancers, and ESS or exonic splicing silencers) and introns (also known as ISEs or intronic

splicing enhancers, and ISSs or intronic splicing silencers) are critical for the correct recognition and combination of exons, by promoting or inhibiting the final assembly.

Figure 1. The alternative splicing machinery. Four main conserved DNA sequence motifs allow the splicing mechanism: the donor splice site GU (5' SS), the acceptor splice site AG (3' SS), the lariat branch point (A) located upstream of the acceptor site and the polypyrimidine tract (PPT) placed between the acceptor site and the branch point. The splicing machinery includes mainly five spliceosomal uridine-rich small nuclear ribonucleoproteins (snRNPs) (U1, U2, U4, U5, and U6), and further auxiliary RNA binding proteins. During the first step of spliceosome assembly, U1 snRNP base-pairs with the 5'-splice site of the pre-mRNA (E complex), whereas U2 base-pairs with the branch-point (A complex). Then, the tri-snRNP complex U4, U5 and U6 associates with the forming spliceosome (B complex), and both U1 and U4 are ejected. This allows U6 to replace U1 at the 5' splice site (C complex) and leads to a U6–U2 interaction that gets close together the 5'-splice site and the branch point, allowing for a transesterification step. At the end, U5 brings near the two exons, joining them through a second transesterification reaction.

Splicing is performed by the spliceosome, a multi-component modular molecular machine composed of five small uridine-rich nuclear RNAs (snRNAs) that tie with proteins to form small nuclear ribonucleoproteins (snRNPs) (U1, U2, U4, U5, and U6) (Figure 1) [6]. The splicing reaction is performed through a coordinated series of RNA–RNA, RNA–protein and protein–protein interactions. During the first step of spliceosome assembly, U1 snRNP base-pairs with the 5'-splice site of the pre-mRNA (E complex), whereas U2 base-pairs with the branch-point (A complex) (Figure 1). Then, a tri-snRNP complex, including U4, U5 and U6, associates with the spliceosome and form the B complex (Figure 1). Hence, both U1 and U4 are ejected, allowing to replace U1 with U6 at the 5' splice site (C complex) (Figure 1). The interaction of U6–U2 gets close together the 5'-splice site and the branch point, allowing a first transesterification reaction. In the end, U5 completes the process by joining the exons through a second transesterification reaction and removing the spliced-out exon [7].

The delicate and finely tuned interplay between the constitutive splicing motifs, the splicing regulatory sequences, the components of the spliceosome and other additional auxiliary RNA-binding proteins allows the occurrence of five major alternative splicing events: exon skipping/inclusion, use of alternative 3' splice site, use of alternative 5' splice site, mutually exclusive exons and intron retention (Figure 2) [2]. This combinatorial assembling of exons increases the number of transcribed mRNAs, and therefore, is able to generate numerous protein isoforms with different biological properties, protein-protein interactions and subcellular localization [8]. AS can also modify enzymatic activity, and even reverse the functional role of the isoforms: for instance, Bcl-X gene is able to produce a long form preventing cell apoptosis and a short form inducing programmed cell death. AS can also occur in non-coding sequences affecting the efficiency of mRNA translation, localization or stability through the “Nonsense-Mediated mRNA Degradation” (NMD) [9] [10].

Figure 2. The alternative splicing mechanism. Five major alternative splicing events are currently known: exon skipping/inclusion, use of alternative 3' splice site, use of alternative 5' splice site, mutually exclusive exons, and intron retention. The splicing events rely on the interplay between the constitutive splicing motifs, the splicing regulatory sequences, the RNA secondary structures, the components of the spliceosome and further auxiliary RNA-binding proteins. However, how the spliceosome decides which exons to include remains currently not clear.

Overall, the AS mechanism works as an on–off switch in gene expression and represents an extremely economical mean to increase protein diversity, explaining the divergence between the estimated 24,000 human protein-coding genes and the 100,000 different proteins that are predicted to be generated [11]. It is a finely-tuned process regulated in time and space, allowing each mRNA to be expressed in specific cellular conditions [12]. The splicing molecular machinery must be both rapid and precise: this is a demanding task considering that introns are usually much larger than exons and that even a single nucleotide addition or deletion will shift the reading frame and modify the encoded protein sequence.

Two types of defects can interfere the AS regulation: mutations of the DNA elements required for correct pre-mRNA processing (called *cis*-acting mutations) or alterations of the factors that are necessary for splicing regulation (termed *trans*-acting defects). *Cis*- and *trans*-splicing aberrations represent direct causative agents of disease or can contribute to disease susceptibility or can modulate disease severity of several neurologic disorders, as we will describe in the next paragraph.

3. ALTERNATIVE SPLICING IN THE NERVOUS SYSTEM AND NEUROLOGICAL DISEASES

AS is particularly widespread in the nervous system. More than 40% of genes are alternatively spliced in brain, meaning an exceptionally high level of splicing events as compared to other tissues [13].

In recent years, our understanding of the fundamental role of AS in neural development and functions has significantly advanced, thanks to the coupling of various computational and experimental approaches [14]. Several studies have suggested that the elaborate and dynamic regulation of AS in the nervous system is critical for modulating protein-protein interactions, transcription networks, and multiple aspects of neuronal development and maintenance [14, 15]. The precise temporal and spatial expression of the highly complex repertoire of isoforms is able to perform complex tasks, such as appropriate connections among billions of neurons that occur during learning and memory processes. It has been demonstrated that the production of particular splice isoforms helps to determine the properties of many different types of neurons, and that several important events during neuronal development are under control of AS mechanisms, including cell-fate determination, axon guidance and synaptogenesis [4]. Splicing events have also been observed in brain areas during whole human lifespan, demonstrating the involvement of more than a third of expressed genes and their link to neural functions [16].

Given the importance of splicing in the nervous system circuits, it is not surprising that an extensive range of different neurological diseases is caused by splicing errors. Alzheimer's disease, Retinitis Pigmentosa, Spinal Muscular Atrophy, Muscular Dystrophy, Ataxia-telangiectasia, Neurofibromatosis, Amyotrophic Lateral Sclerosis, Fragile-X-associated Tremor/Ataxia Syndrome, Prader-Willi Syndrome, Schizophrenia and Autism disorders are directly caused or have an increased risk by either *cis*- or *trans*-acting splicing defects [1, 7, 17–20].

In this broad neurological disorders scenario, the relevance of AS in PD is not still clear, and the splicing mechanisms that regulate PD-related genes remain mostly unknown. In the next paragraphs, we will briefly introduce the genetics of Parkinson's disease, and then we will focus on the splicing regulation of PD-linked genes.

4. GENETICS OF PARKINSON'S DISEASE: BASIC CONCEPTS

Parkinson's disease (PD) is a progressive, debilitating neurodegenerative disorder and constitutes the second most common neurologic disease worldwide after Alzheimer's disease. Clinically, most patients present resting tremor, bradykinesia, stiffness of movement and postural instability. These major symptoms derive from the profound and selective loss of dopaminergic neurons of *substantia nigra pars compacta*. The pathological hallmarks of PD are round eosinophilic intracytoplasmic proteinaceous inclusions termed Lewy bodies (LBs) and dystrophic neurites (Lewy neurites) present in surviving neurons [21].

PD had been for a long time considered a sporadic non-genetic disorder. The identification of distinct genetic loci responsible for rare Mendelian forms of PD has revolutionized this view and has provided new insights to understanding the molecular pathogenesis of this disease [21]. Linkage mapping analysis, genome-wide association studies (GWAS) and next generation sequencing technologies have revealed an increasing number of locus and genes strongly linked to either dominant, recessive and X-linked forms of the disease [22, 23]. For example, mutations in *SNCA* (localized in the *PARK1* locus) and *LRRK2* (locus *PARK8*) are responsible for the development of the autosomal dominant form of PD; *PARKIN* (locus *PARK2*) *PINK1* (locus *PARK6*), *DJ1* (locus *PARK7*) are classified as typical recessive PD genes; mutations in *ATP13A2* (locus *PARK9*), *PLA2G6* (locus *PARK14*) and *FBXO7* (locus *PARK15*) cause the atypical recessive forms; while X-linked forms of PD disease derive from genetic defects in *ATP6A2* and *TAF1* genes. For the sake of completeness, we mention here further monogenic loci, not confirmed genes or risk factors genes (i.e., *PARK3*, *GBA*, *UCHL1*, *PARK10*, *GIGYF2*, *PARK12*, *HTRA2*, *PARK16*, *DNAJ*, *HLA-DR*, *GAK-DGKQ*, *SYNJ1*, *GBAP1*) [23-25]. Some additional genes have also implicated in PD (*SRRM2*, *MAO-B*, *SNCAIP* and *MAPT*) for their altered splicing regulation in PD states.

In the next paragraphs, we will describe the alternatively spliced mRNA variants of PD genes and the current scientific data demonstrating their involvement in PD pathogenesis.

5. ALTERNATIVE SPLICING OF GENES INVOLVED IN THE DOMINANTLY INHERITED FORMS OF PARKINSON'S DISEASE

Several evidences have demonstrated a link between specific genetic mutations and various forms of PD. In general, the inheritance patterns of human disorders are identified by examining the way the disorder is transmitted among the family members. In the autosomal-dominant inheritance, one mutated allele of the gene is enough to cause the disease [26].

Here, we will describe the current literature data about autosomal dominant PD-genes (*SNCA* and *LRRK2*) and the involvement of their splice variants in health and disease. Some additional genes have currently been linked to the development of dominantly inherited forms of PD, such as *VPS35*, *GBA* and *EIF4G1*. However, they will not be discussed since there are no studies that have investigated their AS involvement in the disease.

5.1. *SNCA*

Alpha-synuclein is a small, natively unfolded presynaptic protein, which aggregate to form Lewy bodies, the neuropathological hallmark lesions of PD [27]. *SNCA* was the first gene to be associated to PD family inheritance. Disease-causing mutations of *SNCA* include genetic variations in the coding regions (Ala53Thr, Ala30Pro, Glu46Lys), single nucleotide substitution in 3' UTR and dose-dependent genomic multiplications (duplications or triplications) [27-29]. Some point mutations in splice donor sites have also been reported (IVS2+9A>C) [30].

Figure 3. Exonic maps of the alternative splicing variants of PD genes. Exonic structures of the described mRNA splicing variants are reported in figure. Genes are divided in panels (Red panel: autosomal dominant PD genes; Blue panel: autosomal recessive PD genes; Grey panel: minor PD genes). Each variant is indicated with a number on the left corresponding to the Accession Number reported in Table 1. For some genes, additional mRNA transcripts have been deposited in GenBank but their full-length nature has not been determined. For the complete spectrum of collected mRNAs, the reader is referred to Genome Browser Database (<http://genome.ucsc.edu/>) or Ensemble repository (www.ensembl.org).

Table 1. Alternative splice variants of PD genes. PD genes and accession numbers of the relative splice variants are reported in Table. Genes are divided into three groups (autosomal dominant, autosomal recessive and other PD genes). Numbers in the column “#mRNA variant” corresponds to numbers in Figure 3

SNCA maps on chromosome 4q22.1 and contains 6 exons spanning about 114 kb [29]. These six exons combine to produce the full-length transcript (named SNCA140 from the amino acid size of the protein product) and at least three additional splicing variants (SNCA126, SNCA112 and SNCA98). These latter are generated by in-frame excision of exons 3, 5, or both (Figure 3, red panel and Table 1). SNCA140, 126 and 112 are expressed in a wide spectrum of human tissues, while SNCA98 is probably a brain-specific splice variant with different expression levels in various fetal and adult brain areas [31].

The expression profile of these splicing variants has been investigated and differ in pathological conditions. All four transcripts are over-expressed in PD *frontal cortex* as compared to healthy controls, with a significant up-regulation of SNCA126 [32]. Furthermore, in the *substantia nigra* of affected patients, SNCA126, SNCA112 and SNCA98 are significantly over-expressed [33, 34], whereas in *cerebellum* are present high levels of SNCA112 and SNCA98 [33]. Different expression profiles of *SNCA* variants occur also in other forms of neurodegenerative disorders. For example, in dementia with Lewy bodies and Alzheimer's disease, both SNCA140 and SNCA126 have been found down-regulated and SNCA98 overexpressed. On the contrary, a disease specific regulation has been reported for SNCA112 variant: up-regulation in dementia with Lewy bodies and downregulation in Alzheimer's disease [32, 35, 36]. Additional RNA transcripts with an extended 3' untranslated region have been described and appear selectively linked to pathological processes [37].

Some fascinating data emerge on the SNCA112 variant. PD risk-associated SNPs within the 3' region of *SNCA* gene have been linked to higher SNCA112 level in about one hundred of *frontal cortex* samples. These data suggest the *cis*-regulatory effect of these mutations on splicing mechanism [38]. Expression of SNCA112 is also induced by some parkinsonism mimetics (MPP⁺, rotenone) and oxidant molecules [39]. However, the reason for this biological effect remains obscure.

As anticipated, *SNCA* transcripts produce distinct protein isoforms. The longest transcript SNCA140 encodes for a small protein composed of three separate domains: (1) amphipathic helices at the N-terminal domain conferring the affinity to bind membranes, (2) a central hydrophobic region, named NAC (non-Ab component), which confers the β -sheet potential, and (3) a glutamatergic carboxyl C-terminal domain that is highly negatively charged and prone to be unstructured [27]. Structural characteristics of the shorter isoforms can be predicted based on the exclusion of spliced-out exons. SNCA126 has an interruption on the N-terminal protein-membrane interaction domain [40], SNCA112 is significantly shorter in the unstructured C-terminal region [40], while SNCA98 isoform is a truncated protein consisting almost only of the central region containing NAC [31]. Recently, it has been verified *in vitro* a lower aggregation propensity of the shorter isoforms [41]. In addition, studies with electron microscopy have revealed a different structural organization of these isoforms: SNCA140 proteins aggregate in straight fibrils, SNCA126 isoforms form short fibrils arranged in parallel arrays, while SNCA98 are combined in circular structures [41]. These data may open new perspectives regarding the formation of Lewy bodies induced by alpha-synuclein.

Various functions of alpha-synuclein have been suggested, such as molecular chaperone, regulator of dopamine uptake and homeostasis, inhibitor of phospholipase D2, downregulator of p53 pathway [40] and promoter of the SNARE-complex assembling [42]. Unfortunately, nothing is known about the specific pathophysiological roles of each alpha-synuclein isoform and their relative post-translational modifications (i.e., phosphorylation, nitration, sumoylation,

oxidation, glycosylation, cleavage and ubiquitination), which are known to play significant roles in SNCA functions and regulation [40].

5.2. *LRRK2*

LRRK2 encodes a large 2,527 amino-acid multi-domain protein called leucine-rich repeat kinase 2. The protein contains multiple conserved domains such as a GTPase-like domain (Ras of complex proteins or ROC), the C-terminal of ROC (COR), a kinase domain, and several protein interaction domains (e.g., the leucine-rich repeat - LRR, the WD40 domain, the ankyrin repeat domain and the armadillo repeat region). Although the precise physiological function of *LRRK2* is unknown, it is probably implicated in different cellular functions such as neurite outgrowth, cytoskeletal maintenance, vesicle trafficking and autophagic protein degradation [43].

LRRK2 harbours the most frequent mutations linked to both autosomal dominant inherited late-onset and sporadic PD (i.e., Gly2019Ser and mutations altering codon Arg1441). In addition, several other mutations affecting splice sites have been also observed (IVS19+5_8delGTAA, IVS25-8delT, IVS27-9C>T, IVS30-6C>T, IVS31+3A>G, IVS32+14G>A, IVS33+6T>A, IVS37-9A>G, IVS38+7C>T, IVS46-14T>A, IVS46-8delT) but their pathogenetic role is still under debate [30, 44-51].

LRRK2 transcribes the full-length mRNA and some shorter transcripts, which are composed of a set of exons matching either the central or the final region of the longest form (Figure 3, red panel and Table 1).

Recently, the expression profile of the *LRRK2* splice variants has been studied in the brain of healthy humans by using exon array and RT-PCR methods [52]. Both experiments have detected in *substantia nigra* a transcript without exons 32–33, whereas in *occipital cortex*, *medulla* and *cerebellum* a variant missing exon 32 [52].

Further evidences on *LRRK2* splicing have been observed by Giesert and collaborators [53], who have identified two *LRRK2* splice-variants in mouse brain: one with skipped exon 5, mainly expressed in astrocytes, and another truncated variant terminating with an alternative exon 42a, barely detectable in microglia but extremely expressed in neurons and astrocytes. Protein-structure predictions reveal that the loss of exon 5 may generate a smaller protein with changed affinity for binding partners, whereas the alternative exon 42a may lead to modifications of its enzymatic activity and loss of WD40 domain. Interestingly, the deletion of this domain in the Zebrafish *LRRK2* ortholog (z*LRRK2*) causes a Parkinsonism-like phenotype including loss of diencephalon dopaminergic neurons and locomotion defects [54]. Further studies will need to assess the involvement of *LRRK2* alternative splice variants in PD.

6. ALTERNATIVE SPLICING OF GENES INVOLVED IN THE RECESSIVELY INHERITED FORMS OF PARKINSON'S DISEASE

Some monogenic forms of PD are inherited with an autosomal recessive pattern and, frequently, symptoms have an early onset. In these disorders, mutations in both alleles (either homozygous or compound heterozygous) cause the pathological phenotype [26].

The recessive cases of PD can be clinically classified in typical and atypical forms. Atypical parkinsonism includes a variety of neurological disorders in which patients have some clinical features of PD, but the symptoms are caused not only by neuronal loss in the *substantia nigra*, but also by additional degeneration of cells in other parts of the nervous system such as the striatum.

Here, we will describe the current literature data regarding genes involved in autosomal recessive PD and their AS regulation. We will include genes causing the typical (*PARK2*, *PINK1*, *DJ1*) and the atypical (*ATP13A2*, *PLA2G6*, *FBXO7*) forms of PD.

6.1. *PARK2*

Homozygous or compound heterozygous mutations in *PARK2* (also known as *parkin RBR E3 ubiquitin protein ligase*) are responsible for the 50% cases of autosomal recessive juvenile Parkinsonism (AR-JP), a form of early-onset Parkinsonism characterized by a prolonged response to levodopa and a benign slow course. *PARK2* mutations also explain ~15% of the PD sporadic cases with onset before 45 [55, 56] and are susceptibility factors for late-onset forms (2% of cases) [57]. Along with the about 200 mutations currently identified in *PARK2* coding region, several other point mutations in splice acceptor or donor sites (introns 1, 6, 7, 10, 12, 13 and 16) have been reported [30, 58-64].

PARK2 spans more than 1.38 Mb of genomic DNA in the long arm of chromosome 6 (6q25.2-q27) and contains 17 exons, which are alternatively spliced to produce at least 21 different splicing variants (Figure 3, blue panel and Table 1) [64]. The full length *PARK2* transcript encodes a protein of 465 amino acid [64-66] involved in numerous molecular pathways (protein turnover, stress response, mitochondria homeostasis, mitophagy, mitochondrial DNA stability, metabolism, cell growth and survival) [67]. The expression of multiple parkin isoforms, likely generated by *PARK2* variants, have been observed in different brain areas [68].

The extensive AS of *PARK2* is differently regulated both at transcript and protein level [32, 69-74]. Distinct expression pattern of *PARK2* splice variants has been observed in different tissues and organs including brain and leukocytes [73-77]. *PARK2* protein isoforms show also a differential distribution in human leukocytes [78] and aged brain [79], as well as in different rat and mouse nervous system areas (cerebral cortex/diencephalons, hippocampus, cerebellum, brainstem, striatum, spinal cord, *substantia nigra*) and peripheral tissues (heart, liver, spleen, pancreas, kidney) [80-84]. In addition, a specific expression profile of *PARK2* isoforms have been detected in different tumour tissues [85, 86].

Emerging evidences support the importance of *PARK2* splice variants expression changes in the development of some neurological disease. Differential expression of *PARK2* transcripts have been identified in *frontal cortex* of Parkinson's disease, pure dementia with Lewy bodies, common Lewy body disease and Alzheimer's disease patients as compared to healthy controls [32, 71]. Particularly, a study reports two *PARK2* splicing variants significantly overexpressed in PD [71], whereas another one describes both an increase in the expression level of a parkin splice variant with a simultaneous decrease of the full length transcript in affected PD as compared healthy subjects [72]. The differential and disease-specific expression profiles of *PARK2* transcripts suggest a role of AS mechanism in the development of neurodegenerative disorders.

6.2. *PINK1*

Mutations in *PINK1* (*PTEN-Induced putative kinase 1*) are the second most frequent cause of autosomal recessive early-onset Parkinsonism. They include homozygous or compound heterozygous changes, with a frequency variable from 1 to 9% depending based on the ethnic background [87]. The *PINK1* mutations spectrum involves non sense and missense mutations, insertions or deletions, and whole-gene or single/multiple exon copy number variants located across the entire gene [88].

PINK1 maps on the short arm of chromosome 1 (1p36.12), encompassing ~18 kb of genomic DNA. Its coding sequence is spread over eight exons. In addition to the full-length, only one shorter variant seems to exist matching with the last five exons (Figure 3, blue panel and Table 1).

Some interesting findings emerge regarding the splicing regulation of exon 7. A 23bp deletion disrupting the splice acceptor site of exon 7 has been detected in a sporadic parkinsonian patient, producing several aberrant mRNAs [89]. Moreover, whole exon 7 deletion and a novel U1-dependent 5' splice-site mutation in exon 7 have been found in a large Spanish family with PD members [90].

The *PINK1* protein is a putative serine/threonine kinase of 581 amino acids involved in mitochondrial response to cellular and oxidative stress [91]. In human brain, at least two *PINK1* isoforms are expressed: the full-length protein of ~63 kDa and the N-terminally truncated isoform of 52 kDa [87, 92-94]. An additional isoform of approximately 45 kDa has been detected, although it has not been further investigated [95].

6.3. *DJ1*

Mutations in *DJ1* (also known as *PARK7*) are the less common cause of autosomal recessive Parkinsonism (~1% of early-onset PD) [21, 96]. The first identified mutations were a large homozygous deletion and a missense mutation (L166P) in Italian and Dutch consanguineous families [97, 98]. Subsequently, other alterations including missense mutations in coding and promoter regions, frame-shifts, copy number variations [21, 99] and splice sites changes have been detected [100, 101].

DJ-1 maps on chromosome 1 (1p36.23) and covers seven exons. Two splice transcript variants, differing in the 5' donor site of exon 1, have been identified but encode the same protein. Furthermore, a third cDNA lacking exon 4 and generating a shorter isoform has been isolated (Figure 3, blue panel and Table 1).

The product of *DJ-1* is an highly conserved multifunctional protein belonging to the peptidase C56 family [102]. It acts as positive regulator of transcription, redox-sensitive chaperone, sensor for oxidative stress, and apparently protects neurons from ROS-induced apoptosis [103, 104]. Several *DJ-1* isoforms, which differ for the isoelectric point (pI), have been observed in human brain and peripheral blood [105-108]. However, it has been postulated that the different pI of each protein arises from post-translational modifications of the full-length protein [109]. The expression of these isoforms seems to be altered in PD, and therefore, they have been proposed as potential peripheral blood biomarkers of PD [109].

Interestingly, one of the major binding partners of *DJ-1* in dopaminergic neuronal cells is the splicing factor proline/glutamine-rich (SFPQ protein) [104, 110]. SFPQ, originally

identified as a polypyrimidine-tract binding protein, is part of the spliceosome C complex and is required for *in vitro* splicing of pre-mRNA [104, 110]. DJ-1 binding to SFPQ modulates its transcriptional activity and, therefore, tunes its effect on splicing regulation. DJ-1 mutations could reverberate on its downstream targets, including the splicing factor SFPQ and altering the splicing control.

6.4. *ATP13A2*

ATP13A2 is composed of 29 exons and lies on chromosome 1 covering about 26 kb of genomic DNA. Its mutations are associated with a form of recessively levodopa-responsive inherited atypical Parkinsonism (the Kufor-Rakeb syndrome) [111]. One of the first identified disease-causing mutations was a guanine-to-adenine transition in the donor splice site of exon 13, leading to the skipping of exon 13 and resulting in an deletion of part of the third transmembrane domain [112].

According to databases, at least three transcripts are expressed in humans (Figure 3, blue panel and Table 1). Splice variants 1 and 2 differ only for a nucleotide segment on exon 5, while transcript 3 lacks exons 22 and 28. The *ATP13A2* mRNA is highly expressed in the brain, particularly in the *substantia nigra* of patients with classical late-onset PD [99].

Isoform 1 is a protein of 1180 amino acids with 10 transmembrane domains. Isoform 2 contains a five amino acid deletion near the N-terminus, while isoform 3 contains two deletions, generating a highly diverged C-terminus [112]. Functional studies have shown that the isoform 1 is located in the lysosome membrane, whereas the isoform 3 protein is retained in the endoplasmic reticulum and rapidly degraded by the proteasome. In addition, both isoform 1 and 3 are eliminated via the endoplasmic-reticulum-associated degradation pathway [112]. The full length protein has been recently identified as a potent modifier of the toxicity induced by alpha-synuclein [113].

6.5. *PLA2G6*

Mutations in *PLA2G6* (*phospholipase A2 group VI*) have been recently associated to a particular parkinsonian phenotype consisting of levodopa-responsive dystonia, pyramidal signs and cognitive/psychiatric features with onset in early adulthood [114]. In particular, the c.1077G>A mutation in the terminal nucleotide of exon 7 (apparently a synonymous mutation) stands out as a cause of abnormal mRNA splicing, causing the activation of a cryptic splice site and producing a 4-bp deleted transcript with different frame-shift in leukocytes [114].

PLA2G6 maps on chromosome 22, covering 70 kb of genomic DNA. Several transcript variants have been described up to now, but the sequences of only three of them have been determined (Figure 3, blue panel and Table 1). The longest *PLA2G6* mRNA includes 17 exonic regions and encodes the 85/88 kDa calcium-independent phospholipase, known as A2 isoform a. The other two transcripts differ in the start point, both lacking of exon 9 and encoding the same protein, called isoform b. The expression profile of *PLA2G6* variants in healthy and disease states is still unknown.

6.6. *FBXO7*

Parkinsonian-Pyramidal Disease (PPD or PARK15-associated parkinsonism) is an autosomal recessive neurodegenerative disease with juvenile onset and additional pyramidal signs. It is caused by mutations in *FBXO7* (*F-box only protein 7*). The pathogenic mutations include some missense nucleotide changes (R378G, R498X, T22M) and a compound heterozygous mutation (IVS7 + 1G/T) responsible of the splice donor removal in intron 7 which leads to an aberrant *FBXO7* mRNA [115-117].

FBXO7 contains nine exons and maps on chromosome 22q12.3. It encodes a 522 amino acids protein consisting of several domains targeting proteins for ubiquitination [116]. Several mRNAs have been observed, but only three of them have been completely characterized (Figure 3, blue panel and Table 1) [115]. Transcript 1 is the longest and the most abundant form ubiquitously expressed [118], particularly in skin fibroblasts [119]. Splice variants 2 and 3, both arising from an inner alternative exon 1, differ for the start codon and produce two isoforms of 443 and 408 amino acids, respectively. Both isoforms 1 and 2 have been detected in cells [119], whereas the expression of the third one remains unknown.

7. ALTERNATIVE SPLICING OF OTHER PD GENES

In addition to the above-mentioned pathogenic genes, we will also briefly discuss some others genes (*SRRM2*, *MAO-B*, *SNCAIP*, *MAPT*) implicated in PD pathways and whose splicing regulation is altered during the disease.

7.1. *SNCAIP*

SNCAIP maps on chromosome 5q23.2 and spans about 152 kb of genomic DNA. It encodes Synphilin-1, a presynaptic protein made up of ankyrin-like repeats, a coiled-coil domain and an ATP/GTP-binding domain [120]. Synphilin-1 interacts strongly with alpha-synuclein in neuronal tissue and seems to play a role in the formation of Lewy bodies during neurodegeneration.

The most studied alternative splice variants (Figure 3, grey panel and Table 1) are synphilin-1 and 1A. The first is the full-length transcript, while the second lacks exons 4 and 5, and contains an extra exon located between exons 10 and 11. Synphilin-1A isoform is involved in the pathogenesis of PD and may contribute to the formation of Lewy bodies [121-123]. Accordingly, this protein shows enhanced aggregatory properties causing neuronal toxicity [121-123].

The mRNA expression levels of synphilin 1, 1A and other two additional synphilin variants are simultaneously overexpressed in the *frontal cortex* of PD patients as compared to healthy controls [32, 71].

7.2. *MAPT*

MAPT, which encodes the microtubule-associated protein tau [124], is located on chromosome 17q21 and contains 15 exons. It produces multiple splice transcripts (Figure 3, grey panel and Table 1) which are differentially expressed in human tissues [7]. Specifically, in the adult human central nervous system, *MAPT* splicing is able to create six tau isoforms composed of either three or four microtubule-binding repeat motifs in the C-terminal (3R and 4R-tau).

Several known mutations within and around *MAPT* exon 10 interrupt the exonic and intronic splicing elements as well as the formation of an RNA stem-loop structure at the 5' splice site (which normally functions to restrict spliceosome assembly), resulting in an altered ratio of 3R/4R isoforms [17, 19]. The alteration of this balance causes the hyperphosphorylation and aggregation of tau proteins into neurofibrillary tangles, triggering the frontotemporal dementia with Parkinsonism linked to chromosome 17 (FTDP-17) [17, 19]. These data support a direct relationship between aberrant alternative splicing of tau and neuropathology.

7.3. *MAO-B*

MAO-B gene is located on chromosome X and includes 15 exons (Figure 3, grey panel and Table 1). Several SNPs have been described in populations with different ethnic background [125]. A common SNP associated with two-fold risk of PD is the G/A dimorphism in intron 13 sequence [126-128]. This SNP does not change the coding sequence, and does not affect the consensus acceptor and donor sites. However, it creates a splicing enhancer that stimulates intron 13 removal, spliceosomal complex assembly and modifies the binding site efficiency of splicing factors [125].

7.4. *SRRM2*

Serine/arginine (SR) proteins belong to the class of alternative splicing *trans*-acting factors. One of the SR proteins is the RNA splicing factor SRRM2 (or serine/arginine repetitive matrix 2), which has been identified as the only gene that stood out as differentially expressed in multiple gene expression PD datasets [129].

SRRM2 generates two main alternative splicing transcripts: the full-length isoform containing 15 exons, and the shorter isoform, which contains 11 exons and lacks exons 12–15 (Figure 3, grey panel and Table 1). These two isoforms are differentially expressed in postmortem PD brain [129]. The shorter transcript is upregulated in *substantia nigra* but unchanged in the *amygdala* of PD patients versus healthy controls. On the contrary, the longer transcript is downregulated in both *substantia nigra* and *amygdala* of PDs as compared to controls [129]. In addition, in the peripheral blood of affected patients, the shortest isoform is overexpressed, whereas the longest one is reduced [129].

8. WHOLE-GENOME RNA EXPRESSION STUDIES REVEAL OVERALL ALTERNATIVE SPLICING CHANGES IN PD

Although a “gene by gene” approach may simplify the analysis, global AS changes in PD have to be considered. The majority of large scale gene-expression array studies in the brain of affected patients have actually looked at the full length transcript of each gene by ignoring their multiple splice variants [22]. Nevertheless, AS is significantly altered in cortical neurons of PD patients [130].

In order to specifically explore the splicing expression changes, some studies have used exon arrays which enable an improved monitoring and detection of the AS events. These studies have allowed to observe significant changes of transcript expression profiles in PD blood cells as compared to healthy controls [129, 131]. A similar study was conducted in blood samples of advanced PD patients prior to and following deep brain stimulation which efficiently improves the motor symptoms of PD [132]. This study showed that neurosurgical intervention alters transcripts profiles [132]. Specific splicing variant microarrays have also been used in PD patients in order to detect mRNAs splice variants as molecular biomarkers for an early PD diagnosis. This analysis has allowed to identify 13 splice variants with an altered expression in early-stage PD patients versus healthy controls [133, 134].

Along with microarray technology, AS variants can now be better characterized through RNA deep sequencing (RNAseq) [22]. Whole transcriptome RNAseq data have been obtained from blood leukocytes of PD patients' pre- and post- deep brain stimulation treatment [135]. This method has enabled to identify a large variety of differential splicing events pre and post treatment as well as novel human exons and junctions in protein-coding mRNA transcripts [135]. Based on this first study, RNAseq represents a promising technique to explore PD alternative splicing.

9. EPIGENETIC REGULATION OF PD ALTERNATIVE SPLICING

A growing body of evidence are supporting the role of epigenetics in the development and progression of many neurodegenerative diseases including PD. Epigenetic modifications refer to changes in gene expression through DNA methylation, histones modifications and non-coding RNAs [136]. This latter class of molecules include both long non-coding RNAs (lncRNAs) and microRNAs (miRNAs), which have been suggested as potential modulator factors of AS mechanism in PD.

lncRNAs are described as transcripts longer than 200 nucleotides, and include several spliced transcript collected in the GENCODE non-coding RNA database. lncRNAs expression profiling has been recently investigated in PD leukocytes pre- and post-deep brain stimulation via RNAseq [135]. This study has allowed to identify some lncRNAs overexpressed in PD and inversely decreased following deep brain stimulation [135]. Differentially expressed lncRNA include the spliceosome component U1, supporting the hypothesis of disease-involved splicing modulations [135].

A great number of alternatively spliced exons have also been predicted as binding sites of microRNAs (miRNAs). These are a class of very small non-coding RNA molecules (about 20-22 bp), mainly acting as posttranscriptional modulators of multiple target genes by partial

sequence complementarity. Through this mechanism, they may also influence the activity of the splicing machinery. The interaction between miRNA differential expression and alternative splicing variations in PD has been recently explored [137]. Parallel changes in miRNA profiles and their spliced targets have been detected in PD peripheral leukocytes and in PD-relevant brain regions (including the *substantia nigra* and the *frontal lobe*) through coupled analysis of small RNA sequencing data, splice junction arrays and exon arrays [137].

The characterization of existing links between non-coding mRNAs and AS modifications represents a main step to comprehend the molecular basis of PD.

CONCLUSION

AS is an extremely harmonized process, established by the combination of specific DNA sequences, intronic and exonic elements, regulatory factors and temporal and spatial signaling pathways. Mutations that alter any of these elements may modify the finely regulated splicing processes by varying the assembling or the functions of the encoded proteins and lastly generating the diseases. The comprehension of the role AS in PD may represent an essential point to decipher etiology of this disease. Future studies, both with the standard or the new large-scale methods, will offer a complete data pool of the AS events in PD and will provide new possible insights in order to improve strategies for PD treatment and diagnosis.

ABSTRACT

The microtubule-associated protein (MAP) tau is essential for the development of neuronal cell polarity. Tau protein is preferentially localized in the axon, whereas MAP2, another neuron-specific microtubule-associated protein, is localized in the somatodendritic domain. Previous studies have demonstrated that the localization of these proteins depends, at least in part, on mRNA subcellular localization - of tau mRNA into the axon and MAP2 mRNA into the dendrite.

Tau protein plays a pivotal role in the pathophysiology of Alzheimer's disease, in which its hyperphosphorylation promotes aggregation and microtubule destabilization. Tau undergoes alternative splicing, which generates six isoforms in the human brain, due to the inclusion/exclusion of exons 2, 3 and 10. Dysregulation of the splicing process of tau exon 10 is sufficient to cause tauopathy, and has been shown to be influenced by β -amyloid peptides, while there has been less research conducted on the splicing of other exons.

This study found that the effects of β -amyloid (42) on the alternative splicing of tau exon 2/3 and 6 caused formed cell processes to retract in differentiated cells and altered the expression of exon 2/3 in cell culture. Expression of exon 6 was repressed under β -amyloid treatment. Although the molecular mechanism for this amyloid-tau interaction remains to be determined, it may have potential implications for the understanding of the underlying neuropathological processes in Alzheimer's disease.

Keywords: alternative splicing, RNA, Alzheimer's disease

RNA SPLICING

Eukaryotic cells eliminate introns through RNA splicing. As sequences within RNA that do not code for protein, introns are removed by a structure rich in ribonucleoproteins, known as spliceosome complex. They then join the exonic sequences that produce mature transcript, which migrates from the cell nucleus to the cytoplasm and is then translated into a protein.

The splicing mechanism must be very accurate, since at least 50% of human genetic diseases are associated with mutations that occur in the consensus sequences of the splicing sites. These sequences consist of a 5'-GU and an AG sequence in the 3'-end intron. A region rich in pyrimidines is found toward the end of the 5' intron (CU).

The spliceosome complex must be assembled for splicing to occur. Consensus sequences located in the exon-intron frontier are essential for the 5 ribonucleoproteins (snRNP) U1, U2, U4, U5 and U6 to join these sequences and thus form the spliceosome. This spliceosome consists of several protein complexes. Complex E is created by the binding of U1 to the GU sequence at the 5' site of an intron, the binding of SF1 to the intron branch point, the binding of U2AF1 to the 3' splice site, and the binding of U2F2 to a sequence of polypyrimidines.

Complex A is created when U2 moves to SF1 and binds to the branch point sequence, while Complex B is created when U5, U4 and U6 form a trimer and, together with U5, bind with U2, releasing U1, wherein U5 binds to the intron and exon and U6 binds to the 5' splice site. Complex C is created when U4 is released and U6/U2 catalyze a transesterification process, binding the 5'-end of the intron to the complex to form an intron-lariat structure, with the U5 joining the exon at the 3' splice site and the site is off. U2, U5 and U6 then remain attached to the lariat structure, with the 3' lariat site then cut and the exons linked through ATP hydrolysis. The lariat forms are degraded and the snRNPs are recycled (figure 1).

Figure 1. RNA splicing. Exon 1 flanked on its 3' end by the GU sequence and exon 2 on its 5' end by AG, with both target sites for the ribonucleoproteins and the assembled spliceosome complex. The spliceosome will cut the intron in the consensus sequences and will enable the joining of the exons, generating a mature RNA.

Figure 2. Forms of alternative splicing. A) exclusion or inclusion of exons, B) selection of one or more exons, C and D) competencies by the site of splicing in a particular exon in the region 5' or 3', E) retention of an intron, F) multiple promoters, G) multiple sites poly-A.

In general, through alternative splicing, genes are able to generate a variety of mRNAs (messenger RNA) with the significant biological function of encoding a protein. It has been estimated that at least 90% of expressed genes present alternative splicing.

There are at least 6 circumstances in which alternative splicing is generated: a) the exclusion or inclusion of exons; b) the selection of one or more exons, c and d) competencies by the splice site in a particular exon in the 5' or 3' region, e) the retention of an intron, f) multiple promoters, g) multiple poly-A [1] sites (figure 2). Both exonic and intronic sequences can modulate the splice site through either enhancers or silencer sequences.

ALZHEIMER'S DISEASE

Alzheimer's disease is one of the main genetic diseases associated with alternative splicing.

The most common neurodegenerative disorder occurring in the over 65s [2], Alzheimer's disease (AD) is slow and progressive in nature and is associated with memory loss and behavioral disorders [3].

Symptoms are imperceptible at the onset of the disease, usually for the first 2 or 3 years. There are a few cases of the transmission of chromosomal alterations through autosomal dominant inheritance.

This condition is the most common form of dementia, especially among older people, where it is estimated that the number of cases will reach 135 million people by 2050. When a patient is diagnosed with AD, the pathology will have already progressed for a number of years,

and the disease is, by this point, in its final stages. Although changes occur at least 20 or 30 years before symptoms first appear, it is difficult to detect the disease in advance, as there are no diagnostic tests to confirm these changes.

The pathological processes often linked with AD are premature ageing, amyloid protein deposits, neurofibrillar degeneration, synapse loss, inflammation, metabolic changes, loss of vascular integrity, injury and neuronal loss / neuronal injury and loss.

The degenerative process is neurofibrillary in type and generates nerve cell dysfunction, causing the death of specific neurons in the hippocampus, amygdala, entorhinal cortex and the nucleus basalis of Meynert [4].

Histologically, there are two types of proteinaceous aggregates, the Paired Helical Filaments (PHF) located inside the neuron, and the senile plaques, located in the extracellular space. The PHF include a compact filamentous network formed by aggregates of hyperphosphorylated tau [5], [6], while the senile plaques are formed by peptide β -amyloid deposits [6, 7].

Tau is a protein of the cytoskeleton involved in neuronal morphology and polarity and has the particularity of binding to the microtubules to provide stability and to maintain the neuronal phenotype at the level of the axon [8].

It has been determined that Tau is located in the axon hillock and axon growth cone, given that its mRNA is transported by a protein complex that uses kinesin-3 as a conveyor. It uses the HUD protein as an mRNA stabilizer for the site to which it will be translated [9-11], due to the fact that the mRNA of tau has uridine-rich sequences in its 3'-UTR region of a location in axonal [9,12].

The Tau protein is mainly formed by two domains, the N-terminal, whose function is to interact with the plasma membrane [13], and a C-terminal microtubule-binding domain [14].

The human tau gene is located on chromosome 17 [15]. It is composed of 16 exons and its promoter region that provides neuronal specificity [16].

This gene transcribes three RNAs of 2, 6 and 9 kb that are differentially expressed in the central nervous system depending on their stage of maturity and neuronal type [13]. Six tau mRNA isoforms have been identified through alternative splicing. Five isoforms in the adult central nervous system and one fetal-type isoform. These RNA messengers encode 6 proteins ranging from 352 to 441 amino acids(aa). The fetal isoform (352 aa) does not contain exons 2, 3 and 10. The adult form of 383 aa lacks exons 2 and 3, but does, however, include exon 10. The 381 aa isoform includes exon 2 but not exon 10. The 412 aa isoform includes exon 2 and exon 10, while the 410 aa isoform includes exons 2 and 3, but not exon 10. The 441 aa isoform includes exons 2, 3 and 10 [17] (figure 3).

The alternative splicing of tau occurs in exons 2, 3 and 10, whose form is the type (a) which would correspond to the exclusion or inclusion of exons.

The alternative splicing of tau has been the subject of wide research, most of which has focused on exon 10, which presents a splicing pattern of inclusion and an absence of fetal neurons, and is influenced by exon 9, which promotes inclusion [13]. Exon 10 encodes the second repeat region of Tau (R) (KXGS). Alternative splicing generates isoforms of Tau, 3 or 4 of which are repeated and bind to microtubules. In the mature brain, the levels of repeated 3R and 4R are equal. The disruption of exon 10 is sufficient to cause neurodegeneration or tauopathies [18].

R: Repeat (KXGS)

Figure 3. Tau isoforms, showing the different Tau proteins from the alternative splicing of exons 2, 3 and 10.

Exon 10 is flanked by a long intron of 13.6 kb and a short one of 3.8 kb. Its weak 5' splice site, similar to the 3' site, enables the generation of proteins either with exon 10 or without it [19, 20].

Among the various tauopathies associated with exon 10 (table) that have been studied is Multiple System Tauopathy Disease (MSTD). A neurodegenerative disease with abundant protein tau filaments, this disease belongs to the group of frontotemporal dementia alongside Parkinsonism. MSTD has been reported to be caused by a G to A mutation in the 5' region of exon 10 [21]. This mutation in the splice site is likely to destabilize a stem-loop structure [22] which is involved in the regulation of exon 10 splicing, which in turn might cause an imbalance in the transcripts that include exon 10 and thus affect the amount of repeated microtubule bindings [23].

Another type of dementia related to exon 10 is Frontotemporal Dementia and Parkinsonism (FTDP), which is the most common cause of neurodegenerative disease after Alzheimer's disease. One study found exon 10 mutations in six French families resulting in a Pro→Leu change at amino acid 301. This substitution produces a drastic change in the conformation of the second repeats (Pro-Gly - Gly-Gly) located in the C-terminal of the MAPT protein highly conserved in species [24-26].

Since the late 1990s, research has been conducted on conditions such as: Pick's Disease, which does not include exon 10 or which might include mutations in exon 10; corticobasal degeneration; and, progressive supranuclear palsy, in which the region that encodes exon 10 is hyperphosphorylated (thus preventing Tau from binding to the microtubules) and in which the protein is assembled into filaments [27]. Studies have reported two mutations, Asn279Lys and

Pro301Leu, which are involved in Pallido-Ponto-Nigral (PPND) Disease, by causing neuronal loss in the subcortical nucleus and frontal cortex [28].

Studies conducted in murine models have shown that the deletion of exon 10 leads to an age-associated sensory-motor pathology [29].

While less research has been conducted on alternative exon 2 splicing, studies conducted in our laboratory show that when cell cultures of PC12 (rat pheochromocytoma) are exposed to the β -amyloid peptide 1 $\rightarrow$ 42, they affect the alternative splicing of exons 2 and 3, since immature forms of tau mRNA begin to be transcribed into mature PC12 cells (differentiated neuronal phenotype). Researchers from our laboratory have observed that the processes of these cells begin to retract. Although the mechanism is not yet known, the effect produced in the cells indicates that the immature forms of Tau protein enable the stabilization of microtubules in the processes of these cells [30].

The inclusion of exons 2 and 3 promotes the exchange of immature forms of Tau for mature forms that stabilize microtubules.

Disease	Exon	Mutation	Reference
Multiple system tauopathy.	10	3'GT splice donor	[21]
FTDP-17	10	G272V, P301L and R406W, 5' splice site of exon 10	[23]
Familial frontotemporal dementia and parkinsonism.	10	Pro-->Leu change at amino acid 301	[24]
Neurofibrillary degeneration processes.	10	hyperphosphorylated exon 10-tau.	[27]
Pallido-ponto-nigral degeneration	10	Asn279(Lys) in the PPND	[28]
FTDP-17 mutations.	10	N279K and S305N, increase splicing of exon 10	[25]
Sensorimotor affectation	10	Lack exon 10	[29]
Immature forms of tau mRNA.	2/3	Lack exons 2 and 3	[30]
DM1	2	Lack exon 2	[32]

It has been demonstrated that immature forms of Tau are similar to those found in the FHP [31], which suggests that the exclusion of exons 2 and 3 induced by the amyloid peptide in the AD could destabilize the neurites and thus cause cells to lose their polarity.

A pathology associated with the splicing of exon 2 of tau occurs in human subjects with type 1 Myotonic Dystrophy, which affects two splicing factors, MBLN1 and MBLN2 (muscleblind-like), by preventing the inclusion of exon 2 of tau [32].

Currently the regulation of splicing has been studied by focusing on the microRNAs (miRNAs), which are regulators of gene expression [33]. The miRNAs are short RNA molecules that bind to the transcript in order to suppress and regulate expression. This study found a deregulation of miRNA in the hippocampus and prefrontal cortex, determining that miR-132-3-p was the most altered as the disease progressed. The downregulation of Mir-132-

3-p in neurons was inversely proportional to the emergence of hyperphosphorylated tau [34] and is associated with the splicing of exon 10 [35].

The inclusion of exon 10 is inhibited by such factors as ASF/SF2, SRp55, SRP75 and SWAP [36].

The regulation of exon 2 has been determined by the inclusion and exclusion of exons 2 and 3, thus showing that exon 3 never appears independently of exon 2 [37].

CONCLUSION

Alternative splicing is an important process at a cellular level, since it enables the generation of various RNA messengers from the same gene, producing various proteins.

The regulation of alternative splicing should be performed under strict temporal and spatial conditions, depending on the type of cell and environment to which the cell is exposed.

Around 50% of the diseases have their origin in mutations in the consensus sequences of alternative RNA splicing.

Alzheimer's disease will claim the lives of 135 million people by the year 2050, meaning that this disease is fast becoming a public health problem.

While first world countries are already taking action against this disease, action is not undertaken to this level in third world countries, where this ailment is still not awarded the seriousness it is due. This may be due to the fact that the priorities of third-world populations lie in the development of other areas such as infrastructure, energy, and the economy. In these countries too, however, Alzheimer's disease will also become a serious problem in the future.

Chapter 17

THE ROLE OF SPLICING FACTORS IN CANCER PROGNOSIS AND TREATMENT

ABSTRACT

Alternative splicing is a co-transcriptional mechanism that regulates eukaryotic gene expression that affects almost 90% of the human genes. In this mechanism, different combinations of exons and introns can be identified and removed from the pre-mRNA, allowing multiple mRNA configurations of joined sequences to arise from a single gene, increasing the coding potential of the genome. Alternative splicing events are catalyzed by a large complex known as the spliceosome, which is conformed by more than 300 proteins and ribonucleoproteins. At the catalytic core of the spliceosome, the small nuclear ribonucleoproteins (snRNPs) U1, U2, U4, U5 and U6 are found. The auxiliary factors responsible for the fine regulation of this mechanism include two major groups: the SR proteins and the hnRNP family.

Malfunctions of alternative splicing events can affect the natural expression of a large number of transcripts, including several factors involved in apoptosis or cell survival, molecular processes intimately associated with cancer evolution. In many cases, specific splicing factors or mutated components of the splicing machinery are linked to an anomalous event. Moreover, a switch in specific splicing factors occurs in particular types of cancer where the concomitant outcome is the production of non-functional proteins with added, deleted, or altered domains affecting tumorigenesis.

With all this evidence, several strategies have been developed to regulate alternative splicing in which central or auxiliary splicing factors are the target of modulatory molecules. Given the combination of elements needed to regulate alternative splicing, the mechanisms underlying the functional and physiological implications of these tools are also diverse. Collectively, these strategies are intended to improve cancer prognosis, therapeutic and treatment.

INTRODUCTION

mRNA processing is a key maturation mechanism that includes mRNA splicing, polyadenylation and capping. One of the key steps in the maturation process is alternative splicing, a nuclear co-transcriptional process that regulates eukaryotic gene expression. Initially, the extent of splicing was underestimated but it is currently established that almost 90% of mammalian genes undergo some splicing event, explaining in part the enormous coding potential of the human genome [1]. Malfunctions in this mechanism can generate different diseases, including rare disorders, neural conditions and cancer [2]. Unfortunately, it has been difficult to establish a precise correlation between one mutation and the correspondent alternative splicing event due to the transitive nature of gene expression. Moreover, a particular splicing event can be regulated differently according to the cell context, developmental stage or specific requirements [3].

General Splicing Mechanism

The general mechanism that regulates alternative splicing is presented in figure 1. During splicing, exonic or coding sequences are included while intronic or non-coding elements are excluded from the mature messenger RNA. This decision is determined by a large protein complex called the spliceosome, conformed by more than 300 proteins and ribonucleoproteins [4]. The catalytic center of the spliceosome is composed by the small nuclear ribonucleoproteins (snRNP) U1, U2, U4, U5 and U6.

Splicing regulation involves the recognition of *cis* elements coded in the pre-mRNA molecule. The main regulatory elements include the 5'ss and the 3'ss, which are located at the borders of the intron. The 5'ss is recognized by the snRNP U1. Close to the 3'ss, a pyrimidine-tract and a Branch-point sequence (BPS) can be also recognized by the snRNP U2 and some auxiliary factors. After the initial recognition, conformational changes and two consecutive trans-esterification reactions culminate with exon ligation catalyzed by snRNP U5 originating a mature product where introns have been removed. For human genes, conserved sequences have been detected for the 5'ss, the 3'ss, the polypyrimidine tract and the BPS. Depending on the location of these sequences along the pre-mRNA and how conserved they are, their relative strength can determine if these splicing signals are recognized during a precise splicing event. In many cases, a single-nucleotide mutation can alter one of these splice signals, activating maybe some other splicing signals and producing an aberrant mRNA or a non-functional protein.

In addition to the *cis* elements described above, other regulatory elements can improve or modulate the recognition of some splicing signals. These supplementary sequences can improve the recognition of a specific splice site and in this case we call them enhancers; they are called silencers when its activity block some splicing event. These sequences are either located at the exonic regions or coded inside the introns (Figure 1). Depending on their function and location, we can recognize Exonic Splicing Enhancers (ESE), Exonic Splicing Silencers (ESS), Intronic Splicing Enhancers (ISE) or Intronic Splicing Silencers (ISS). These regulatory elements are recognized by additional splicing factors, which will be further presented.

Mutations can also occur along these regulatory sequences with the same final outcome of aberrant mRNA or protein generation.

Figure 1. Alternative splicing mechanism and modulation. Alternative splicing occurs in the nucleus, where the core splicing factors (snRNPs) and regulatory proteins (SR and hnRNP families) bind consensus sequences in the pre-mRNA in order to produce mature mRNAs that will be later exported and translated in the cytoplasm. SR proteins will generally recognize exonic splicing enhancers (ESE) and hnRNPs could bind intronic splicing silencers (ISS). These events could be modulated by different molecules, like spliceostatin (SSA) that would change the final outcome of the splicing event. SSA interacts with SF3b complex of snRNP U2. Different types of oligonucleotides can also modulate splicing. These oligos can use carriers like CPP in order to enter the cell.

Splicing Regulatory Factors

The auxiliary factors responsible for the fine regulation of this mechanism include two major groups: the SR proteins [5] and the hnRNP family [6].

The SR proteins belong to a family of highly conserved splicing factors that has been described in vertebrates, fungi and plants. These factors possess a protein-interacting domain called RS due to its high content of arginine and serine residues and an RNA-interacting domain [5]. Initially, SR proteins were identified as splicing activators given their ability to recognize ESEs and recruiting the spliceosome to the adjacent intron. The activity of SR proteins in a specific cell context depends on several conditions, including its particular expression and concentration in that precise cell type and its phosphorylation status, which alters protein

conformation, RNA-binding or protein-binding capabilities, resulting in changes on spliceosome assembly and catalysis.

On the other hand, more than 20 heterogeneous nuclear ribonucleoproteins or hnRNPs have been identified and they comprise a family of RNA-binding proteins that possess diverse biological functions including splicing regulation and have been named alphabetically depending on their apparent mass from hnRNP A through hnRNP U [6]. In general, hnRNP proteins have shown predominantly antagonistic functions from SR proteins. In this regard, the ability of hnRNPs to prevent the recognition of the pre-mRNA by the snRNPs or SR proteins has been documented several cases. Since the initial evidence from *in vitro* studies where hnRNP A1 and SRSF1 showed the opposite effect over splice site selection [7] several investigations supported this observation [8, 9]. This antagonistic behavior has been observed also in cancer tissues [10]. However, further evidence supports the notion that hnRNP A1 and hnRNP F/H can facilitate the splicing of a long intron [11] arguing the common assumption that hnRNP proteins are splicing inhibitors.

Despite their specific function concerning alternative splicing decisions, splicing factors share several features that are relevant for their function, including their ability to bind RNA, to shuttle between the nucleus and the cytoplasm, to produce different protein variants due to alternative splicing and to interact with other proteins. Moreover, splicing factors have been involved in several co- and post-transcriptional events responsible for gene expression, including nuclear export, non-sense-mediated decay and translation [12]. This global relationship between splicing and further events can explain the relevant role of splicing decisions in cancer events and in cellular fate [13].

Summarizing, splicing regulation involves the cis-acting elements that correspond to sequences coded in the pre-mRNA, which can be recognized by trans acting factors where the core proteins are the snRNPs. The relative position of the cis elements can alter splicing selection. In addition to this combination, auxiliary factors that belong to the SR and hnRNP families can contribute to splicing decisions. Finally, the availability of central and auxiliary splicing factors, according to their expression, concentration and phosphorylation status may alter the splicing choice. The complex nature of splicing regulation correlates well with the precise nature of gene expression control.

Alternative Splicing and Cancer

It was initially believed that splicing was a rather exceptional mechanism. However, a growing amount of evidence supported the notion that alternative splicing governs the expression of the majority of human genes [14]. After these observations, the important contribution of alternative splicing in human disease was acknowledged and more recently its determinant role in cancer was widely recognized [15, 16]. For example, it has been shown that hereditary mutations linked to cancer predisposition in the BRCA1/2 genes are related to alternative splicing regulation [17, 18].

In general, alternative splicing events that have been associated to cancer are active during tumor progression and reinforce metastases, which is the cause of 90% of all human cancer casualties [19]. Normally, the expression of a specific splicing isoform that is linked to tumor progression can be detected in normal tissues as well, but once that cell homeostasis is lost, alternative splicing can provide an advantageous background for tumor progression. In this

regard, it is well documented that the splicing of various genes is altered during oncogenic progression and it can be related to the development of cancer features, like an increase in proliferation, vascularization and invasion [19, 20].

In several cases, changes in splicing profiles in tumors are related to the altered activity, expression level or even mutations in regulatory splicing factors. Like many regulatory factors in the cell, splicing regulators undergo a wide range of post-translational modifications. These modifications have been studied mainly for SR proteins and include phosphorylation [21,22], methylation [23, 24] and sumoylation [25]. These post-translational modifications have an impact not only on splicing regulation, but also on different aspects of cellular physiology. Phosphorylation of splicing factors SRSF1 and SRSF5 affect splicing of fibronectin 1 (FN1) [26], caspase 9 [27] and PKC β II [28]; these splicing decisions can affect tumor progression. These phosphorylation effects are not general or redundant and they vary according to the cancer type and the splicing factor involved [29].

Mutations in the Core Splicing Machinery Related to Cancer

The real impact of somatic mutations in genes coding components of the splicing machinery has not been thoroughly analyzed. However, several examples have been deposited in the International Cancer Genome Projects Database (CGPD). As it can be observed in table 1, the record deposited in this database indicates that there are 102,603 mutations in genes related to splicing, affecting a total of 5,949 donors. Unfortunately, the exact correlation between a precise mutation and its functional implication remains to be elucidated. According to the results obtained from 51 projects deposited in the CGPD, 361 genes coding for splicing factors are mutated in all types of cancer. The most frequently mutated genes include hnRNP proteins (NOVA1, hnRNP M, hnRNP C, hnRNP A2/B1, hnRNP F, RALY), SR proteins (SRSF4, RBM39, Tra2 α , Tra2 β) and SR-protein kinases (SRPK1 and SRPK2), RBM proteins (RBM4, RBM5) and auxiliary splicing factors.

Interestingly the only snRNP components affected seem to be some U2-specific factors (SF3A1, SF3A2, SF3A3, SF3B1, SF3B2, SF3B3 and SF3B4) and the U1-specific protein U170K (SNRNP70). Amongst these genes, the most frequently occurring mutations lie at the SF3B1, U2AF1, RALY hnRNP and SNRNP70 genes (Table 2). On the other hand, splicing mutations have been detected in patients from all types of cancer, but individuals with the highest number of mutations in the greatest number of genes are related to liver, pancreas, skin and breast cancer (Table 3). All these data strongly support the relevant function of alternative splicing in cancer, but the precise mechanism underlying each gene and factor regulation remains to be elucidated.

Concerning particular cases where precise alternative splicing events have been further studied, there are some well-documented cases. For example, it has been reported that recurrent mutations are found in genes that code for splicing factors SF3B1 and U2AF1 [30] in myelodysplastic syndromes (MDS). This group includes myeloid neoplasms with altered myeloid blood cell production and disposition to progress into acute myeloid leukemia. SF3B1 is also frequently mutated in chronic lymphocytic leukemia (CLL) [31, 32, 33], as well as in uveal melanoma [34, 35]. All SF3B1 mutations are heterozygous, and none are nonsense mutations or introduce a frameshift.

Table 1. Distribution of cancer types related to splicing

Project	Site	Tumour Type	Tumour Subtype	# Donors affected	# Mutations	# Genes
PRAD-CA	Prostate	Prostate cancer	Adenocarcinoma	124 / 124 (100.00%)	1,692	290 / 361 (80.33%)
RECA-EU	Kidney	Renal cancer	Renal cell carcinoma (Focus on but not limited to clear cell subtype)	95 / 95 (100.00%)	2,936	335 / 361 (92.80%)

SF3B and U2AF1 participate in splice site selection and mutations in these genes could affect 3'ss recognition. It has also been observed that in some cases, these mutations can correlate with intron retention, leading to speculate that this defect on splicing could be related to nonsense-mediated mRNA decay (NMD). However, the final outcome may depend on the gene in which alternative splicing is regulated and on the specific cellular context. For example, it has been reported that in HeLa cells, while the expression or mutant SF3B induces intron retention, mutant U2AF1 activates cell death [30]. The relevance of cell context for splicing decisions is also supported by additional evidence, given the observation that patients with MDS carrying SF3B1 mutations have usually a favorable prognosis, whereas SF3B1 mutations in CLL correlate with poor survival and resistance to chemotherapy [32, 33, 36, 37, 38]. Likewise, mutations on the spliceosomal core have also shown a different effect in pediatric MDS and juvenile myelomonocytic leukemia [39]. This cellular-context dependency of effects provides an opportunity for developing antitumor drugs that could elicit a response only in tumor but not in normal cells. Moreover, this specificity could also partially explain why some chemotherapeutic agents are more effective in specific cancer types.

Cancer-Related Changes in Splicing Factors Expression

As it was mentioned earlier, SR proteins are splicing regulators that usually bind ESEs and facilitate splicing. The first SR protein discovered and one of the best-studied splicing factors is SRSF1. It has been observed that this factor is overexpressed in several human cancer cell

lines. In addition, several genes related to cell cycle progression and oncogenic transformation, are known targets for SRSF1. Further details concerning the particular mechanism by which SRSF1 regulates cancer progression will be presented later. SRSF3 is another overexpressed SR protein for several human cancers and knocking down this gene can lead to apoptosis in different cancer cell lines [40, 41].

Phosphorylation of SR proteins is an important determinant of their localization and activity [42] and this regulation of SR protein activity by phosphorylation has now been implicated in a cancer-associated AS event.

Table 3. Most Frequent Mutations in splicing genes reported for individuals with cancer

hnRNP proteins were initially described as negative regulators of splicing, and the original findings suggested that these proteins are splicing inhibitors. hnRNP A1 and hnRNP A2 have been long related to cancer regulation, mainly according to its ability to recognize and protect telomeric sequences [43]. These factors are also overexpressed in a wide variety of cancers and the silencing of these genes can also induce apoptosis. This effect seems to be cancer-related, given that it has not been observed in normal cells [44, 45, 46]. In terms of splicing, it has been found that more than 2000 alternative splicing events could be regulated either by hnRNP A1 or A2 proteins [47] and some of the shared targets are related to metabolic abnormalities relevant for tumor cell promotion [48].

hnRNP I (also known as PTB) was initially related to the exclusion of an alternative exon through the recognition of an ISS element [49]. A neural variant of this splicing factor was identified [50] and a global analysis showed that this factor, currently known as NOVA, regulates several neural splicing events, where the inclusion or exclusion of the alternative exon would depend on the position of the binding site for this factor [51]. This position-dependent regulation has been also demonstrated for other hnRNP proteins [11]. In agreement with these observations, genome-wide studies in HeLa cells revealed that PTB can either repress or activate exon inclusion, depending on the location of its binding site [49, 52], suggesting that the differential regulation can also occur in cancer cell lines and that it may have a role in cancer progression. According to its relevant function in the brain, high levels of hnRNP I have been found in gliomas [44, 53] and it might facilitate progression of astrocytic tumors [54]. hnRNP H is also up-regulated in gliomas and the silencing of this gene produces cell death in glioma (U373) and HeLa cells [55].

RBM family of proteins are also involved in splicing regulation. Currently, fifty proteins are classified as RBM (RNA-binding proteins) factors in the HUGO Gene Nomenclature Committee Database. The most widely studied of these RBM proteins, including RBM4, RBM5, RBM9 and RBM17, are involved in RNA processing, specifically in pre-mRNA splicing regulation [56-58]. RBM factors are components of the spliceosome that modulate alternative splicing of a number of genes by modulating splice site pairing after recruitment of the U1 and U2 snRNPs to the 5' and 3' splice sites of the intron. Particularly, RBM5, RBM6 and RBM10 are highly similar RNA-binding proteins that in some cases can show redundant functions [56]. RBM5 has shown the ability to positively and negatively modulate apoptosis by regulating the alternative splicing of several genes involved in this process, including FAS and CASP2/caspase-2. In the case of FAS, RBM5 promotes the exclusion of exon 6, which in turn produces a soluble form of FAS that inhibits apoptosis. In the case of CASP2/caspase-2,

RBM5 promotes the exclusion of exon 9 and generates a catalytically active form of CASP2/Caspase-2 that promotes apoptosis [59]. RBM10 overexpression correlated with elevated levels of the soluble isoform of TNF- α (sTNF- α) and with an increase in apoptosis [58], supporting its function as an apoptosis modulator and cytokine expression regulator.

The functionality of RBM proteins varies in different cancer types and a better understanding of the role played by these paralogs in the regulation of the expression levels for different genes may contribute to the production of more effective therapies for a wide collection of diseases, including cancer.

Splicing Regulators That Have Been Considered Oncogenes or Tumor Suppressors

Over the last few years, several splicing factors attracted special attention due to its oncogenic properties, like SRSF1 [60], SRSF9 [61], hnRNP A1/A2 [62] and hnRNP H [63]. The strongest evidence supporting the oncogenic effect of a splicing factor has been provided for SRSF1, given that its over-expression induces sarcomas in nude mice [59]. The oncogenic activity of this particular splicing factor could be related to the following molecular events related to the multi-factorial regulation of SRSF1 expression. It has been shown that the well-studied oncogene Myc activates the transcription of SRSF1 through two E-boxes and this activation correlates well with an increase of several splicing variants that are well-known targets of SRSF1 and that are consistent with an oncogenic phenotype [64]. On the other hand, SRSF1 controls the alternative splicing of the tumor suppressor BIN1, which in turn blocks the activity of Myc [65]. In this same sense, knocking-down SRSF1 reduces Myc's oncogenic activity [64] while its up-regulation has been observed in different types of tumors, including lung and breast. Overexpression of the two proteins SRSF1 and Myc results in breast epithelial cell-transformation and the accompanying effect is an increase in the activity of the translation factor eIF4E [66].

The tumor promoting activity of SRSF1 has been linked to its first RNA-recognition motif (RRM1), which controls the alternative splicing of several cancer-related genes, like BIN1, MNK2, S6K1, the apoptotic gene BIM [60] and it increases the expression of B-Raf, which in turn activates the MEK/ERK signaling pathway. In accordance with this, MEK1 inhibition blocks the transformation mediated by SRSF1 [67]. Furthermore, SRPK1 is a protein kinase responsible for SRSF1 translocation to the nucleus, whose transcription can be repressed by the tumor suppressor WT1 [68], supporting the link between SRSF1 location and its activity in cancer.

SRSF1 expression can be also regulated through alternative splicing and by micro-RNAs. At least six variants of SRSF1 can be generated through alternative splicing out of which one generates the full-length factor and the other five generate aberrant products. These aberrant products could be targets for NMD due to the generation of premature termination codons. Moreover, SRSF1 has the ability to auto-regulate the splicing of its own pre-mRNA and it can also down-regulate its own expression [69], indicating the high and multifactorial control of its expression. A direct link between SRSF1 expression and cancer derives from the observation that the Leukemia/lymphoma-related factor (LRF) is an oncogenic transcription factor that represses miR-28 and miR-505 [70] and these two miRNAs bind the 3'UTR of SRSF1 mRNA. In accordance to this, a reduction in LRF generates a decrease in SRSF1 expression [71].

Considering all these, the 3'UTR of SRSF1 is a good target for fine regulation either by miRNAs or by NMD and it is not rare that its regulation can have an important effect on further cellular processes, like those implicated in cancer and other diseases.

Regulation of Proto-Oncogenes by Splicing Factors

The activation of proto-oncogenes is one of the key features of the initial stages of cancer. There are some examples where alternative splicing events show a strong effect on the activity of some proto-oncogenes. We will further discuss some of the best-documented examples corresponding to Cyclin D1 and H-ras.

Cyclin D1 regulates cell cycle progression through its association with CDK4/6 [72]. It is currently known that cyclin D1 pre-mRNA possess two alternative polyadenylation sites and each isoform produced has different oncogenic activity. The more common product is the full-length peptide Cyclin D1a, where the 5 exons of the pre-mRNA are included. The alternative isoform is Cyclin D1b, which utilizes a polyadenylation site in intron 4 [73]. Both isoforms have the ability to interact with CDK4 and to regulate its activity in a similar fashion. Cyclin D1b is up-regulated in breast and prostate cancer [74, 75]. One of the main differences between the two isoforms consists on its cell localization: while Cyclin D1b resides in the nucleus, D1a shuttles between the nucleus and the cytoplasm according to the cell cycle progression. This difference could be related to the loss of a phosphorylation site at the C-terminus of Cyclin D1, which is target for the glycogen synthase kinase β [76, 77]. This site has been mutated and the result is the constitutive nuclear localization and a more oncogenic activity [78], in accordance to the functional effect observed for the alternative isoform Cyclin D1b. Regarding splicing regulation of this pre-mRNA, a common polymorphism located near the 5'ss of exon 4 seems to be responsible for this alternative decision [73, 79]. The G870A polymorphism lies at the last nucleotide of exon 4 and may affect exon 4 recognition by the spliceosome, favoring polyadenylation at an intronic position and producing isoform D1b. Binding sites for the splicing factor Sam68 have been identified in intron 4 and a correlation between Sam68 expression and D1b production has been reported [80]. A similar correlation was observed for SRSF1 [81]. Moreover, the G879 allele is associated with an increased risk for different types of cancer, supporting the relevance of D1b production in tumorigenesis [72].

The H-Ras proto-oncogene is another example of alternative splicing regulation affecting proliferation that occurs when an intronic mutation generates an increase in H-ras expression, augmenting the transforming potential of this gene [82]. This mutation disrupts the 5'ss of the alternative exon IDX [83]. H-Ras pre-mRNA can be alternatively spliced in the IDX and 4A terminal exons, yielding the p19 and p21 proteins, respectively. IDX inclusion generates an in-frame stop codon that could be a target for Non-sense Mediated mRNA Decay (NMD). As mentioned before, alternative products can show different cell localization: H-Ras p19 localizes in the nucleus and binds p53, but it can also bind p73 and promote its transcription [84]. In agreement with this, knocking down H-Ras p19 increases proliferation in different cell lines [85, 86]. p19 also induces FOXO1 and a delay in G1/S phase, which correlates with the hypophosphorylation of both Akt and p70SK6, leading to the maintenance of a reversible cellular quiescence state and preventing apoptosis [87]. hnRNP A1 and the RNA helicase p68 inhibit IDX inclusion through the interaction with an ISS located downstream of the alternative exon [88]. On the other hand, hnRNP H, SRSF2 and SRSF5 promote IDX inclusion [89].

Some splicing factors have been linked to the modulation of some apoptosis-related transcripts and could be considered as apoptosis regulators. This is the case of TIA-1/TIAR factors. TIA-1 and TIAR are highly conserved mammalian proteins [90] that show similarity with U1 snRNP-associated protein Nam8 from *Saccharomyces cerevisiae* and its ability to regulate alternative splicing events has been demonstrated [91, 92, 93]. TIA-1/TIAR favors the production of the proapoptotic form of Fas [94] and increases proliferation of HeLa cells [95]. Besides, TIA-1 and TIAR regulate alternative splicing of exon IIIb in the fibroblast growth factor receptor 2 (FGFR2) pre-mRNA and they regulate the inflammatory response under stress conditions by silencing the translation of TNF- α and COX-2 [96, 97]. These observations strongly suggest the important role of TIA-1/TIAR in growth and survival of cancer cells and its role in cancer progression.

The Role of Alternative Splicing in Cancer Progression

As discussed earlier, alternative splicing regulates the expression of diverse genes that show important roles in tumor progression and invasion. The determinant role of splicing factors has been already summarized and it results evident how splicing genes and factors could correlate with cancer progression. Moreover, there are several genes that are associated with metastasis and invasion, which are targets for alternative splicing. Diverse cell processes involve alternative splicing regulation of key genes, modulating almost every aspect of cell fate (Figure 2). We will further present different examples of determinant alternative splicing events that could be related to cell invasion and metastasis.

CD44 is a transmembrane protein with a rather complicated pattern of alternative splicing, which involves 10 adjacent alternative exons that can be included solo or in combination [98]. CD44 was one of the first genes for which AS was shown to be altered by signaling pathways associated with growth, involving Ras signaling and Ras–Raf–MEK–ERK pathway [99, 100], where ERF phosphorylated the splicing factor Sam68, which in turn activates the inclusion of exon v5. This finding was relevant because for the first time the connection between a mitogenic signaling pathway and splicing control was demonstrated [101].

FGFR genes encode four closely related tyrosine kinases receptors and FGFR1-3 show several mutually exclusive exons that can produce different proteins according to the cellular context and development through alternative splicing [102]. hnRNP proteins, mainly hnRNP A1, F/H and PTB are involved in the regulation of these splicing events [103-105].

Rac1 transcripts can also generate alternative splicing isoforms with important repercussions in cancer cells. Rac1 pre-mRNA is alternatively spliced to produce Rac1 and Rac1b. While Rac1 activates transcription by NF κ B and AKT kinase [106-107], Rac1b includes the internal 57-nt exon 3b and shows less GTPase activity but high GDP/GTP exchange [108]. Rac1b has exhibited a tumor-specific expression in colorectal and breast tumors and is up-regulated in metastatic tissues [109, 110]. When splicing regulation of this event was studied, it was found that SRSF1 overexpression resulted in increased exon 3b inclusion, while SRSF3 and SRSF7 had the opposite effect [111] and Wnt/ β catenin pathway appeared to be involved [112].

Figure 2. Alternative splicing and cell biology. Almost any kind of gene can be a target for alternative splicing and this mechanism can influence practically every cellular mechanism that could be related to cancer progression and tumorigenesis.

Alternative splicing of Ron transcripts has also been related to the invasive phenotype in cancer cell. Under normal conditions, Ron stimulation activates signaling pathways that enhance invasive growth [113, 114]. An alternative variant lacking exon 11 (Δ -Ron) and several isoforms have been found in epithelial cancers, including colorectal and breast cancer; the expression of these isoforms correlates with metastasis [113, 115]. The production of Δ -Ron is regulated by SRSF1 [113] and it has been proposed that Ron splicing is a key event responsible for the effect of SRSF1 in promoting metastasis [116, 117].

Closely related to metastasis, angiogenesis is a key hallmark of cancer and VEGFA, which promote the formation on new blood vessels in tumors, presents several transcripts that are alternatively spliced quite frequently [118]. In this case, SRSF1, SRSF5 and SRSF6 contribute to the production of the pro-angiogenic form of VEGFA [119].

Therapeutic Tools Developed to Regulate Splicing Factors Activity and Cancer

Considering the high impact of alternative splicing on gene expression, different molecular tools have been developed in order to correct or redirect aberrant splicing events [120]. The initial strategies applied to regulate alternative splicing focused on modifying this process using nucleic acids or nucleic acids analogs such as short oligonucleotides, which could be designed either to silence or to enhance the expression of a particular gene (Figure 1). These nucleic acids analogs could be single stranded antisense oligonucleotides with a complementary sequence for a specific region in certain gene. This molecule has the ability to target a specific mRNA and regulate its expression. Usually, the confirmation of this regulation is tested both

in vitro and *in vivo*. In some cases, these oligonucleotides include a sequence that is complementary for a regulatory element contained in the mRNA. These elements could be targets for auxiliary proteins, like SR and hnRNPs or they could be mutated sequences and restoring the wild-type sequence could alleviate the normal splicing regulation. For example, an oligonucleotide directed to regions located at or close to a splice site can mask normal or aberrant splicing events leading either to exon exclusion or inclusion and an artificial oligo could correct this aberrant event. In order to increase the half-life of these molecules and their resistance to nucleases, modulatory oligonucleotides have been modified being more effective due to a longer life into the cell. One modification involves their association with peptidic adapters, which are called peptide-nucleic acids (PNAs). Another chemical modifications include phosphorodiamidate morpholino oligos (PMOs), 2'-OMe (2'-ortho-methyl) or splice-switching oligonucleotides (SSOs). All these molecules are effective *in vitro* and some of them have been tested in several clinical trials. The most common diseases in which the treatment involves splicing modulatory molecules correspond to different types of atrophies. In order to increase availability, it has been necessary to develop some strategies to introduce the nucleic acid or analog into the cell, such as cell-penetrating peptides (CPPs), which are based on antimicrobial peptides and have been successfully applied (Figure 1). CPPs like Penetratin and Transportan are efficient delivery vectors that have been tested both *in vivo* and *in vitro* to carry several splicing-regulatory oligonucleotides with high efficiency and low toxicity [121].

Microbial derivatives like Spliceostatin (SSA) are newly discovered molecules that modulate alternative splicing and have shown effective anti-proliferative and anti-cancer activities [122]. Spliceostatin was identified in *Pseudomonas* sp. No. 2663, but since this initial discovery, similar molecules have been isolated from different bacterial strains [123, 124]. Spliceostatin mechanism of action involves the interaction with an essential component of the spliceosome, SF3b (Figure 1). Herboxidiene is another molecule that targets the spliceosome and inhibits proliferation. In HeLa cells treated with herboxidiene, translation of the intron 1–containing pre-mRNA leads to production of a C-terminal truncated protein isoform p27*, which is resistant to proteasomal degradation and inhibits CDK2 kinase activity, thereby inhibiting cell growth [125]. SSA treatment also leads to intron retention in VEGF and results in reduction of VEGF levels (possibly by NMD), inhibiting cancer cell angiogenesis [126]. Although the exact mechanism of selective tumor cytotoxicity remains to be fully explored, one explanation is that growth of cancer cells often relies on oncogenic protein isoforms (arising from alternative splicing), which are lacking in normal cells.

CONCLUSION

Alternative splicing is already a sophisticated mechanism of precise regulation. The key elements of this process are the central and accessory splicing factors. The role of alternative splicing in cancer becomes more and more studied and there is increasing evidence linking gene regulation to cancer diagnosis, progression and treatment. The implication of splicing factors in cancer still is under development. Further insights in the genetic origin of cancer, the splicing factors interacting with particular genes and its relationship to eukaryotic gene expression regulation could provide additional information that may be applied to several aspects of cancer. Moreover, splicing factors could be considered as new drug targets for many

diseases, including cancer. According to the importance of this mechanism and the general repercussions of this process in cell fate, it becomes logical that the development of different molecules and compounds to modulate alternative splicing should occupy immediate research. Technical improvements and additional basic studies could provide the appropriate tools to fight this prevalent disease.

Benemérita Universidad Autónoma de Puebla, Puebla, México

ABSTRACT

The precise control of protein production is essential for the appropriate cell physiology and survival. However, single mutations or accidentally introduced errors can occur during the flow of genetic information. In eukaryotic cells, some messenger RNA (mRNA) molecules leave the nucleus after splicing but further mechanisms are involved in the ultimate outcome of the correspondent protein. One of such systems corresponds to the mRNA surveillance network that includes nonsense-mediated mRNA decay (NMD), an important quality control system that ensures the accuracy of transcripts, to maintain a healthy cellular homeostasis. NMD eliminates anomalous mRNAs harboring premature termination codons (PTCs) to prevent the production of potentially harmful truncated proteins, but it can also regulate the steady state of many physiological mRNAs. Targets for NMD are sometimes linked to mutations or introduced errors but the vast majority can be generated as a result of alternative splicing.

The key components required for NMD include the UPF and SMG proteins. These factors interact with a set of proteins (the exon junction complex or EJC) that are deposited just upstream of exon-exon junctions after mRNA splicing and orchestrate a regulated mechanism in order to identify PTCs and either sequester these mRNAs or target them for degradation. Some of these factors are linked to particular disorders and could be modulated in order to correct the defect.

The NMD pathway is physiologically and medically important, because an escape from NMD can result in severe clinical phenotypes. Consistent with this, it is estimated that more than 60% of human genes have alternatively spliced products that generate at least one PTC isoform and that approximately 30% of inherited genetic disorders are caused by nonsense mutations or by frameshifts that generate nonsense codons. Initially associated as a genetic cause for beta-thalassemia, the NMD process has expanded from the haematopoietic system and it has reached different kind of human disorders, including

cystic fibrosis, Duchenne muscular dystrophy, Hurler syndrome, recessive spinal muscular atrophy and polycystic kidney disease. Finally, it is predicted that some cancers are aided by NMD and the repression of this mechanism may be a potential target for the treatment of certain cancers. In this regard, pharmacological agents have been developed for the treatment of diseases caused by premature stop mutations, including aminoglycosides, but the whole therapeutic potential of NMD targets to correct genetic disorders remains to be exploited.

INTRODUCTION

During the flow of gene expression, there are several co- and post-transcriptional events that ensure fidelity of the information and the functionality of the generated products. In eukaryotes, transcription is not only responsible for the synthesis of the mRNA, but it also includes the co-transcriptional maturation of the pre-mRNA corresponding to the 5' capping, splicing and 3' end formation. Altogether, these three processes occur while a pre-mRNA is still associated with a transcribing RNA polymerase II leading into an export, translation and decay pathway. Once in the cytoplasm, eukaryotic cells possess several quality control mechanisms to ensure the fidelity of gene expression, including the Nonsense-mediated mRNA decay (NMD) pathway.

Initially, NMD was described as a surveillance mechanism that detects and degrades mRNA containing premature termination codons (PTCs). This event was first reported for humans and *Saccharomyces cerevisiae* in 1979 [1, 2] and later it was also found in other analyzed eukaryotes, such as *Caenorhabditis elegans* [3], *Drosophila melanogaster* [4] and plants [5]. After these initial observations, it was also demonstrated that NMD not only targets PTC-containing mRNAs, but it can also sequester inappropriately spliced transcripts [6]. Moreover, it is now established that there are several types of mRNA molecules that can be targets for NMD, including some noncoding RNAs, mRNAs that contain an upstream open reading frame or a 3'UTR that contains an intron, selenocysteine codons during selenium depletion and mRNAs with an unusually long 3'UTR [6]. In this regard, several bioinformatic analyses suggest that more than 60% of human genes have alternatively spliced products that generate at least one PTC isoform [7]. Accordingly, the production of some of these PTC-containing isoforms and its degradation by NMD was experimentally validated [8, 9]. However, the physiological and pathological significance of NMD in terms of human health remains largely obscure.

Initially, PTC-generating mutations were linked to beta-thalassemia, but after this initial discovery, the number of mutations linked to NMD has been growing. The official report from the National Organization for Rare Disorders (NORD), considers nearly 7000 known rare genetic disorders and it is believed that 30% of these disorders occurs due to a nonsense or frameshift mutation that creates a PTC [10, 11].

NMD MECHANISM

In all eukaryotes studied, NMD requires a set of conserved regulatory factors [12], where the core components of the NMD machinery are the UPF proteins: UPF1, UPF2 and UPF3 [13

– 15] which are highly conserved. In multicellular organisms, NMD requires four additional NMD factors: SMG1, SMG5, SMG6 and SMG7, which regulate the phosphorylation state of UPF1 [6], controlling its functionality during NMD. When these four genes were mutated in *C. elegans*, morphological defects were observed in the male bursa or in the hermaphrodite vulva, giving rise to their name: Smg or suppressor of morphological defects on genitalia [16]. Besides these central proteins, a growing list of trans acting NMD factors has been described, which can vary among species. In mammals, the NMD pathway includes the components of the exon-junction complex (EJC) and SURF complexes, some Cap (CBP20 and CBP80) and PolyA binding proteins, splicing factors and components of the mRNA degradation pathway [17]. Despite the great conservation of some of these factors in different organisms, their expression and distribution fluctuates across species and even when various mechanistic models have been proposed [18, 19], we will focus here in the model established for human (Figure 1).

Figure 1. NMD mechanism. After splicing, EJC complex are deposited along the mRNA molecule. If a PTC is detected, the NMD machinery stops translation and arrests the mRNA. After this recognition, UPF1 and UPF2 are recruited to the complex and the ribosome is disassembled from the mRNA. Finally, degradation of the aberrant mRNA involves different decay processes and nucleolitic activities.

In mammals, the UPF2 and UPF3 proteins associate with the EJC, comprised by the Y14, MAGOH, eIF4AIII and MLN51 proteins. This EJC is normally deposited 20-24 nucleotides upstream of most exon-exon junctions during pre-mRNA splicing [20-22]. The classic NMD

route is usually triggered during the so-called pioneer round of translation when a nonsense codon lies at 50-55 nucleotides upstream of an EJC that has been deposited by the splicing machinery. The relative position of the stop codon determines how sensitive the mRNA could be to NMD or even if it can escape from degradation in many mammalian mRNAs. Moreover, this differential sensitivity for NMD could correlate with the severity of the disease [23]. PTC recognition occurs due to the formation of the SURF (SMG-1/SMG-8/SMG-9, Upf1 and eRF) complex at sites containing a PTC-recognizing ribosome and a downstream EJC. The transiently formed SURF complex detects the downstream EJC and forms a DECID complex, activating UPF1 through phosphorylation by SMG1. The SMG-5/SMG-7 complex uncouples UPF1 from the ribosome and release factor and finally SMG-6 promotes UPF1 dissociation from the mRNA (Figure 1). At the end, mRNA degradation is initiated by deadenylation in mammals and when approximately 110 nt have been deadenylated, mRNA is degraded from both ends with the additional involvement of the cleavage by the endonuclease SMG-6 [6].

NMD FACTORS RELATED TO PARTICULAR DISEASES

The most relevant evidence supporting the role of NMD in human genetic diseases comes from patients with developmental neural disorders that carry mutations in the UPF3B gene. Genetic studies in families with multiple affected individuals have demonstrated that mutations in UPF3B are related to the intellectual disability of these individuals and in many cases some patients present concomitant psychiatric disorders, including schizophrenia or autism [24-27].

Besides the UPF3 mutations discussed above, UPF2 has been also associated with neural and developmental disorders [23]. Particularly, heterozygous deletions of genomic regions that include UPF2 have been linked to clinical phenotypes and a de novo missense mutation was detected in a patient with schizophrenia [28]. An interesting study of copy number variations including 18 known NMD and EJC genes associated these genes with neurological disorders, where UPF2 or RBM8A were associated with various neural disorders, along with congenital abnormalities in some cases [29]. Genomic irregularities in UPF3A, SMG6, EIF4A3 or RNPS1 have also been associated with disorders related to neurological or psychiatric disorders.

Another NMD factor that has been strongly associated to several diseases is Y14, which is a core component of the EJC system that functions in NMD, translational enhancement and mRNA metabolism. In the EJC core, Y14-Magoh directly interacts with eIF4AIII and inhibits its ATPase activity to elicit the interaction between the EJC and the mRNA [30] and this association remains after the export to the cytoplasm [31]. The critical role of Y14 in NMD was confirmed by the observations that depletion of this factor impairs the degradation of transcripts that contain PTCs [32]. Besides its role in NMD regulation, Y14 enhances translation [33, 34], augments PRMT5-mediated methylation of Sm proteins *in vitro* [35] and inhibits mRNA decapping [36]. Additional functions of Y14 include the production of anti-apoptotic forms for the alternatively spliced genes Bcl-x, Bim and Mcl1 [37] and cell cycle control [38]. Considering all the relevant functions of Y14 in mRNA biogenesis and in translation, it is reasonable to presume that it could be related to some pathological conditions. In this regard, Y14 has been implicated in the thrombocytopenia-absent radius (TAR) Syndrome, which occurs when one RBM8A allele that encodes Y14 is deleted and a deleterious regulatory SNP (single-nucleotide polymorphism) is found in the other allele [39, 40]. TAR

patients have low numbers of platelet precursors in bone marrow and mental retardation [41-43]. Thus, Y14 may regulate the expression of hematopoietic cells and in brain development [44].

Even when a clear correlation between an NMD factor and a particular disease has been established only in a few cases, it could be tempting to suggest that there is a more sophisticated interconnection between the NMD machinery and several cell processes related to human disorders.

GENETIC DISEASES LINKED TO NMD

The first evidence indicating that a PTC could be related to a decrease in mRNA translation for a mammalian gene came from studies of β -globin transcripts from patients with β -thalassemia [45, 46]. In normal conditions, hemoglobin is a tetramer integrated by two α -globin and two β -globin subunits. In the common recessive form of β -thalassemia, the human β -globin mRNA contains PTCs at the 5' portion in both copies of the β -globin mRNA, which are targets for NMD. In this situation, free α -globin is degraded and less amount of functional hemoglobin is formed, generating severe anemia in the patient. On the other hand, when PTCs are located in the last exon of the β -globin mRNA, these anomalous forms are able to escape from NMD leading to the production of truncated proteins that result in the symptomatic dominantly inherited anemia [47]. β -thalassemia is one of the few genetic diseases where the effect of NMD has been extensively studied; however it is possible to propose that a similar effect could occur in some other diseases, like susceptibility to mycobacterial infections caused by mutations in the IFNGR1 gene [48], brachydactyly type B and Robinson syndrome that are caused by mutations in the ROR2 gene [49], von Willebrand disease [50], factor X deficiency [51] and retinitis pigmentosa associated to mutations in the CRX gene [52].

Another interesting example of a genetic disease that could be related to NMD is osteogenesis imperfecta (OI). The main cause of OI is sequence variation in the genes COL1A1 and COL1A2, which code for the α 1- and α 2-chain of collagen type 1. Sequence variations at the exon-exon junction could result in exon skipping or to the insertion of PTCs, which could in turn lead to NMD. OI caused by PTCs resulting from single-base substitutions is confined to the COL1A1 gene where a total of 39 unique variants have been recorded, suggesting that COL1A2 PTCs may be generally recessive and under-reported. Mutations in exons 50 and 51 create PTCs through frameshifts in the last exon, which will not result in NMD, creating a dominant negative effect of the disease [53].

RELEVANCE OF NMD IN HUMAN CONDITION

Considering the increasing amount of evidence, it is now clear that NMD is a key regulator of gene expression. The relevance of NMD for cell viability is also supported by the observations concerning lethality of knocking-down key NMD factors in different species [12]. Moreover, mouse embryos that are inactive for NMD resorb shortly after implantation and NMD-inactive blastocysts undergo apoptosis in culture shortly after plated [54].

As mentioned before, mutations in the Upf3b human gene generate intellectual disabilities and neurological conditions, including autism, hyperactivity disorder and schizophrenia. Besides, a large number of diseases including cystic fibrosis, different types of dystrophy and several groups of cancer that are generated because of the presence of PTCs. It was estimated that 12% of all mutations reported in the Human Gene Mutation Database, generated a premature stop codon [55]. If all mutations are considered, including deletions, insertions and splicing mutations, the amount of events that can induce an aberrant product that could be target for NMD increases to almost 30% of all genetic diseases and cancers [11]. Overall, the estimated frequency of PTC inclusion in mRNA molecules due to different causes, strongly suggests that NMD seems to have a huge impact on human health.

Regulation of the activity of several NMD factors can originate differences in NMD accuracy depending on the specific transcript, cell type or tissue in which the regulatory event occurs. This context can in turn show a modulatory effect on the NMD outcome. Generally, NMD protects the cell from aberrant, dysfunctional and potentially toxic peptides that could generate from the mutations depicted above. However, in some cases the truncated proteins produced by PTC-containing mRNAs can still possess, at least in part, its normal function. In these cases, NMD degrades the truncated product that could partially rescue the related phenotype, as demonstrated for Ullrich's disease [56].

Table 1. Most frequently mutated NMD genes in cancer patients

Symbol	Name	Location	Type	# Donors affected	# Mutations
SMG1	SMG1 phosphatidylinositol 3-kinase-related kinase	chr16:18816175-18937776	protein_coding	468 / 3,239 (14.45%)	613
SMG6	SMG6 nonsense mediated mRNA decay factor	chr17:1963133-2207065	protein_coding	464 / 3,239 (14.33%)	787
SMG7	SMG7 nonsense mediated mRNA decay factor	chr1:183441351-183567381	protein_coding	456 / 3,239 (14.08%)	601
RPS9	ribosomal protein S9	chr19:54704610-54752862	protein_coding	434 / 3,239 (13.40%)	506
UPF2	UPF2 regulator of nonsense transcripts homolog (yeast)	chr10:11962021-12085169	protein_coding	382 / 3,239 (11.79%)	486
SMG5	SMG5 nonsense mediated mRNA decay factor	chr1:156219015-156252620	protein_coding	248 / 3,239 (7.66%)	290
RPL37A	ribosomal protein L37a	chr2:217362912-217443903	protein_coding	241 / 3,239 (7.44%)	330
PABPC1	poly(A) binding protein, cytoplasmic 1	chr8:101698044-101735037	protein_coding	233 / 3,239 (7.19%)	241
EIF4G1	eukaryotic translation initiation factor 4 gamma, 1	chr3:184032283-184053146	protein_coding	229 / 3,239 (7.07%)	261
PPP2R1A	protein phosphatase 2, regulatory subunit A, alpha	chr19:52693292-52730687	protein_coding	222 / 3,239 (6.85%)	238

Regarding cancer, it is believed that some carcinomas could be reinforced by NMD abnormalities. Cancer cells commonly show abnormalities in processes like DNA repair, DNA damages, cell cycle progression and apoptosis making reasonable to propose that point and frame-shift mutations can accumulate in tumors, contributing to proliferation and malignancy. This observation could be related to non-essential genes.

Table 2. Most frequent mutations occurring in NMD genes reported for different cancer patients

However, NMD could still contribute to cell homeostasis by degrading aberrant products produced from essential genes that would be otherwise toxic [57]. Other possibility is that NMD affect the expression of cancer-associated genes by modulating the quantity of splicing variants produced by these genes. Even when this observation needs to be further demonstrated, there is some evidence suggesting that PTC-containing splicing variants of some tumor-suppressor genes could be targets for NMD, like BRCA1, TP53 and WT1. According to the information deposited in the International Cancer Genome Projects Database (CGPD), the most frequently

mutated NMD genes correspond to different SMG proteins (Table 1). A total of 13,243 mutations have been reported for NMD genes in individuals with cancer and some of the genes with higher number of mutations are UPF3A, SMG7, SMG1 and UPF2 (Table 2).

THERAPIES FOR NMD-RELATED DISEASES

In order to treat diseases caused by premature stop mutations, one possibility is to reduce the efficiency of translation termination to restore the production of some full-length functional proteins. In eukaryotes, translation termination occurs when the stop codon enters the ribosomal A site. Stop codon recognition is mediated by the eukaryotic release factor 1 (eRF1) instead of the codon-anticodon interaction that occurs during translation. Upon this recognition, eRF1 triggers the release of the nascent polypeptide from the peptidyl-tRNA located in the P site of the ribosome [58]. Usually, eRF1 competes with a near-cognate aminoacyl-tRNA, which is able to bind the ribosomal A site even when it contains only two of the three nucleotides of the stop codon. Under different conditions, the incorporation of near-cognate aminoacyl-tRNAs can be stimulated in order to convert stop codons into sense codons [59]. This process is named “termination suppression” or “readthrough”. When this occurs at the PTC that is in frame, the synthesis of the full-length protein continues restoring the proper expression and the event is called “stop codon suppression” or “nonsense suppression”. This natural-occurring process may be exploited to provide a therapeutic tool for patients with genetic disease (Figure 2). Several molecules have been shown to induce “nonsense-suppression” both *in vitro* and *in vivo*, including aminoglycosides (gentamicin, amikacin, tobramycin), modified aminoglycosides (NB30, NB54, NB84), ataluren (PTC124) and RTC13. Demonstrated targets for these molecules comprehend cystic fibrosis (CF), Becker and Duchenne muscular dystrophies (BMD/DMD), spinal muscular atrophy, ataxia telangiectasia, Rett syndrome, Usher syndrome type I, Hurler syndrome, Maroteaux–Lamy syndrome, infantile neuronal ceroid lipofuscinosis, cystinosis, X-linked nephrogenic diabetes insipidus, carnitine palmitoyltransferase 1A, hemophilia, methylmalonic aciduria, neuronal ceroid lipofuscinosis, peroxisome biogenesis disorder (PBD), obesity, poor drug metabolism, and cancer [60]. Aminoglycosides have also shown an effect suppressing nonsense mutations in the tumor suppressor genes p53 and ATM [10]. Some disorders have moved to the stage of clinical trial using suppression therapy, like CF, BMD/DMD, factor VII deficiency, Hailey–Hailey disease, hemophilia A and hemophilia B, leukocyte adhesion deficiency 1 and McArdle disease [61, 62].

Unfortunately, many aminoglycosides used for nonsense suppression possess important risks, like reversible nephrotoxicity and permanent ototoxicity, which have been developed in 2-25% of patients treated with these molecules [62]. Additional efforts have been pursued in order to reduce aminoglycoside toxicity. For example, the concomitant administration of aminoglycosides with various antioxidants or polyanions has shown reduced toxicity [63, 64]. Another successful approach has been to encapsulate aminoglycosides in liposomes [65], but its application for suppression therapy will need more adjustments [66]. Finally, careful monitoring and dose regulation have been also implemented to reduce toxicity, without sacrificing the therapeutic effect [67].

Figure 2. Read through process. Under normal conditions, when a PTC is detected, the NMD machinery is recruited to the mRNA to be degraded. In this case, a truncated version of the protein is produced and a symptom or phenotype can be observed. When an aminoglycoside or a similar molecule (pink circle) interacts with the ribosome, the stop codon can be overlooked and a functional protein can be synthesized, alleviating the symptom caused by the mutation that inserted the PTC.

Table 3. Clinical and preclinical studies evaluating the activity of ataluren

DISORDER OR DISEASE TYPE	DISORDER OR DISEASE NAME	Status	REFERENCE
Muscle Disorders	DMD	Licensed in EU and European Union	74-77
	Miyoshi myopathy	Preclinical study	78
Ion Channel Disease	Cystic Fibrosis	Licensed in EU and European Union	79-86
	Long QT syndrome	Preclinical study	87
Neurological Disorders	Infantile Neuronal Ceroid Lipofuscinoses (INCL)	Preclinical study	88, 89
	Late Infantile Ceroid Lipofuscinoses (LINCL)	Preclinical study	88
	Ataxia telangiectasia	Preclinical study	90

Table 4. Genes affected by NMD showing important differences in clinical phenotype

Gene symbol	Gene name	PTC location	Phenotype	References
COL1A1	Collagen type I, alpha 1	5' PTC	Osteogenesis imperfecta type I	102, 103
		3' PTC	Osteogenesis imperfect type II-IV	
COL2A1	Collagen type II, alpha 1	5' PTC	Stickler syndrome	102,104
		3' PTC	Spondyloepiphyseal dysplasia	
DMD	Dystrophin	5' PTC	Duchenne muscular dystrophy	105, 106
		3' PTC	Becker muscular dystrophy	
FBN1	Fibrillin-1		Marfan syndrome and type 1 fibrillinopathies	107, 108
		5' PTC	More severe	
SALL1	Sal-like 1	5' PTC	Milder phenotype	109
		3' PTC	Townes–Brocks syndrome	
GHR	Growth hormone receptor	5' PTC	Growth hormone insensitivity syndrome	110
FGD4	Frabin		Charcot Marie Tooth disease type 4H	111, 112
		5' PTC	Less severe	
HEXA	Hexosaminidase A		Tay-Sachs disease	113
		5' PTC	Infantile (severe)	
RB1	Retinoblastoma		Retinoblastoma	114
		5' PTC	Early onset	
ATM	Ataxia-telangiectasia mutated	5' PTC	Mild	115
		3' PTC	Severe	
HBB	beta-Globin gene	5' PTC	Recessively inherited beta-Thalassemia major	116-119
		3' PTC	Dominantly inherited beta-Thalassemia intermedia	
IFNGR1	Interferon gamma receptor 1	5' PTC	Mycobacterial infection recessively inherited susceptibility	120, 48
		3' PTC	Mycobacterial infection dominantly inherited susceptibility	
ROR2	Receptor tyrosine kinase-like orphan receptor 2	5' PTC	Robinow syndrome (recessive)	49, 121
		3' PTC	Brachydactyly type B (dominant)	
VWF	von Willebrand factor	5' PTC	Recessively inherited type 3 von Willebrand disease	50
		3' PTC	Dominantly inherited type 2A von Willebrand disease	
F10	Coagulation factor X	5' PTC	Bleeding tendency associated to factor X deficiency (recessive)	51
		3' PTC	Bleeding tendency associated to factor X deficiency (dominant)	
RHO	Rhodopsin	5' PTC	Retinitis pigmentosa (recessive)	122, 123
		3' PTC	Retinitis pigmentosa (dominant)	
CLCN1	Chloride channel 1	5' PTC	Becker disease	124
		3' PTC	Thomsen disease	
CRX	Cone-rod homeobox-containing gene	5' PTC	No homozygotes to date, normal heterozygotes	52
		3' PTC	Leber congenital amaurosis (dominant)	
ABCC6	ATP-binding cassette, subfamily C member 6	5' PTC	Pseudoxanthoma elasticum (recessive)	125
		3' PTC	Pseudoxanthoma elasticum (dominant)	

In addition to developing alternative strategies to reduce aminoglycosides toxicity, the designing of novel molecules that are safer for nonsense suppression have demonstrated encouraging results. Modified molecules like Ataluren, RT13 and RT14 provide additional structural scaffolds to develop novel, safe and nontoxic drugs with increased efficacy. For example, Ataluren (PTC124) has shown low toxicity and has been approved by the Food and Drug Administration (FDA) and the European Medicines Agency (EMA) for the treatment of DMD and CF originated by nonsense mutations [68]. Ataluren has also been tested in several preclinical studies for different rare disorders [69-73], which are summarized in Table 3.

Even when nonsense suppression has shown promising results, its application as a more general therapy could be limited due to the specific genetic and cellular context. For example, it is possible that the introduction of the random amino acid can generate missense mutation that could still fail to rescue the activity of the full-length protein. In some cases, it has been reported that a full- or nearly full-length protein generated by nonsense suppression can activate a T-cell mediated immune response.

CONCLUSION

NMD relevance for human health is starting to be discovered. Several rare disorders have been linked to NMD (Table 4). Moreover, even when a PTC could be located in any part of the mRNA, it appears that a correlation exists between the PTC position and the strength of the disease. In many cases, so-called silent mutations correlated with a particular phenotype and after NMD discovery, it results clear that many of these point mutations inserted a PTC, generating in many cases a severe disease. With all the information available and summarized here, it results clear that NMD is a relevant mechanism for human health. However, an important amount of diseases that may be targets for NMD remain to be studied. Fortunately, some therapeutic tools have been developed to treat some of the NMD-related diseases. Even when the general strategy for modulating NMD has been applied with success, an enormous effort will be necessary in order to discover the molecular details underlying several genetic diseases and the therapeutic tools that could be applied to correct the defects.

ABSTRACT

Alzheimer's disease (AD) is the most common type of dementia in the elderly population with a higher prevalence in women. Memory impairment and cognitive decline in AD are primarily linked to its neuropathological hallmarks, i.e., cholinergic neuronal atrophy and death, presence of intraneuronal neurofibrillary tangles and accumulation of amyloid β ($A\beta$) deposits within the extracellular senile plaques. Consequently, genes encoding $A\beta$, tau and proteins involved in $A\beta$ procession received the most careful scientific attention. However, a growing body of evidence suggests that AD pathogenesis is not limited to the changes of AD genes' expression, but also depends on their alternative splicing. Therefore, the present review focuses on data concerning alternative splicing changes in AD.

First of all, pivotal AD genes (APP (amyloid precursor protein), tau, presenilin 1 (PS-1) and 2 (PS-2) and apolipoprotein E (APOE)) have a number of splice variants with divergent functions that are differentially expressed in AD and normal brain tissues. Second, alternative splicing of genes involved in $A\beta$ processing and metabolism is also affected in AD. This group includes BACE-1 (β -site APP cleaving enzyme 1), nicastrin and APL-1 which are components of the γ -secretase complex, AIDA-1 (protein that binds to the intracellular domain of $A\beta$ PP following cleavage by γ -secretase; FE65 (binds to the cytoplasmic tail of β PP). Finally, splice variants of such candidate AD genes as acetylcholinesterase (cholinergic deficit is one of the central mechanisms in AD development), estrogen receptor α (ER α) (estrogen deficiency is one of the predisposing to

* Corresponding Author's Email: T.Ishunina@nin.knaw.nl (Ishunina T.A., MD, PhD, Associate Professor, Department of Histology, Embryology, Cytology, Kursk State Medical University, Karl Marx Street 3, 305041 Kursk, Russia).

AD factors), BDNF (brain derived neurotrophic factor that is crucial for neuronal survival and synaptic transmission) and its receptor TrkB, excitatory aminoacid transporter 2 (EAAT2) (colocalized with tau in dystrophic neurons), genes of the ion channels and neurotransmitter receptors, synapsin, RCAN-1 (regulator of calcineurin), neuronal GFAP, ubiquilin-1 (related to the proteasomal degradation of proteins and interaction with PS-1 and PS-2) and genes involved in the regulation of the cell cycle and apoptosis (CIZ1, DENN/MADD) should be considered as important elements of the AD pathogenesis.

Together, these data show that a lot of changes in alternative splicing are intimately linked to AD, which should be, thus, considered as a disorder with compromised and disregulated splicing events.

INTRODUCTION

Alzheimer's disease (AD) is the most common cause of dementia with a higher prevalence in women. Cognitive decline in AD was found to be correlated to hyperphosphorylated tau (neurofibrillary tangles, (NFT)) and A β deposits (senile plaques) (Duyckaerts et al., 2009). Therefore, genetic studies focused on genes encoding tau, A β and proteins involved in A β procession. A growing body of evidence suggests that alternative splicing of these genes is closely related to AD pathogenesis, and, in particular, to sporadic or spontaneous cases (Mills and Janitz, 2012). In the present review splice variants of following AD-related genes will be presented: 1) pivotal genes associated with inherited predisposition to AD (tau, APP (amyloid precursor protein), presenilin 1 (PS-1) and 2 (PS-2) and apolipoprotein E (APOE); 2) genes involved in A β processing and metabolism: BACE-1 (β -site APP cleaving enzyme 1), nicastrin, APH-1 (anterior pharynx defective), AIDA-1 (AID-associated protein 1), clusterin, FE65; 3) other candidate AD genes: acetylcholinesterase, tissue transglutaminase (tTG), estrogen receptor α (ER α), BDNF (brain derived neurotrophic factor), TrkB (tropomyosin receptor kinase B), excitatory aminoacid transporter 2 (EAAT2), genes of ion channels and neurotransmitter receptors, synapsin, synphilin-1, RCAN-1 (regulator of calcineurin), neuronal GFAP (glial fibrillar acidic protein), ubiquilin-1, CIZ1 (CDKN1A interacting zinc finger protein 1), DENN/MADD (differentially expressed in normal and neoplastic tissues MAPK-activating, death domain protein), DBI (diazepam-binding inhibitor).

Alternative Splicing of Pivotal AD Genes

Tau

Tau protein is crucial for microtubule assembly in neurons (Uversky, 2009). In AD tau is abnormally phosphorylated, N-truncated and accumulated in the neurons in the form of neurofibrillary tangles (Duyckaerts et al., 2009). The distribution of tau deposition in the brain progresses in a stepwise way from the entorhinal cortex and hippocampus to isocortex and the visual cortex as the last affected areas, providing the basis for Braak staging of AD (Braak and Braak, 1991). The tau gene contains 16 exons, from which exons 2, 3 and 10 are alternatively spliced. In the human brain 6 tau isoforms were identified that are different in the number of 29 amino acids inserts at the N-terminal part (encoded by exons 2 and 3) and three (3R tau, exon 10 missing) or four repeat (4R tau, exon 10 is present) regions at the C-terminus: Δ 2,3,10 (exons 2,3 and 10 deleted); Δ 3,10 (exons 3 and 10 deleted, exon 2 present); Δ 10 (exon 10 is

skipped, exons 2 and 3 present); $\Delta 2,3$ (exons 2 and 3 missing, exon 10 present); $\Delta 3$ (exon 3 is skipped, exons 2 and 10 present); isoform with exons 2,3 and 10 present) (Goedert et al., 1989; Buee et al., 2000; Wang and Liu, 2008; Wolfe, 2009; Uversky, 2009). Isoforms without exon 10 are known as 3R tau ($\Delta 2,3,10$; $\Delta 3,10$; $\Delta 10$), whereas those retaining this exon are called 4R tau. Exons 2 and 3 encode the N-terminal domains that are important for microtubule spacing in axons and for the interaction of tau with the plasma membrane. Exon 10 encodes an additional microtubule binding repeat (4R tau) that is involved in microtubule interactions (Buee et al., 2000). Tau variants lacking exons 2 and 3 appeared to be present at different stages of rat neuronal development and were suggested to contribute to plasticity in the adult rat brain (Collet et al., 1997). Alternative expression of exon 10 plays an important role in the pathogenesis of various tauopathies (i.e., frontotemporal lobe degeneration, progressive supranuclear palsy and corticobasal degeneration) in which the ratio of 4Rtau to 3R tau isoforms is altered. In control subjects these tau isoforms are equally distributed with a ratio 4R tau/3R tau being around 0.48 (Ingelsson et al., 2007). In AD brain both 4R tau and 3R tau are present with a notable abundance of 4R tau isoforms. Levels of exon 10 containing tau mRNAs (4R tau) were elevated in affected brain areas of sporadic AD cases (Glatz et al., 2006; Niblock and Gallo, 2012). Furthermore, exon 10 immunoreactivity (indicating the presence of 4R tau) was demonstrated in intracellular NFT (Ishizawa et al., 2000). Although there were no significant differences in 4R tau/3R tau mRNA ratio in CA1 hippocampal neurons and entorhinal cortex between AD and control groups in the study of Ingelsson et al. (2006), methodological issues should be taken into account (Conrad et al., 2007). Detailed analysis of exons 2, 3 and 10 showed an increased incidence of exon 10 inclusion and exon 2 exclusion in the temporal cortex of AD cases leading to the overexpression of $\Delta 2,3$ 4R tau (Conrad et al., 2007). Taken together, the data indicate that abnormal splicing of tau mRNA resulting in the overproduction of 4R tau isoforms is one of the mechanisms by which tau accumulates in the AD brain. These alterations were not related to tau gene mutations. Therefore, pharmacological or biological agents that are involved in the regulation of tau alternative splicing may be used to delay the progression of neuropathology in AD (Zhou et al., 2008; Niblock and Gallo, 2012).

More recently, 6D and 6P tau isoforms with unique 11 amino acid sequences resulting from alternative splice sites at the end of exon 6 were identified (Lapoint et al., 2009). They contain only the N-terminus and a part of the proline-rich region. 6D and 6P isoforms lack the MTBR region that is essential for tau-microtubule binding and tau aggregation. Both of these splice variants were detected in all brain areas, including the cerebral cortex and the hippocampus. Interestingly, 6D protein expression was particularly high in the human cerebellum that is not affected by tau neuropathology and was very low in the hippocampus and cerebral cortex that are known tangle-prone regions (Luo et al., 2004). Moreover, 6D did not co-localize with neurofibrillary tangles reinforcing the idea about its neuroprotective role. In a functional study, indeed, 6D and 6P isoforms were shown to inhibit polymerization of the full-length tau, and were suggested to be endogenous inhibitors of tau filament formation (Lapoint et al., 2009). In conclusion, a loss in coordination of tau alternative splicing may be an important contributing factor to the pathogenesis of AD (Glatz et al., 2006; Conrad et al., 2007; Niblock and Gallo, 2012) (figure 1).

Figure 1. Influence of different tau splice variants on NFT accumulation.

APP (Amyloid Precursor Protein) Gene

In the amyloid plaques in the brain of AD patients APP-derived A β is a main constituent. The APP gene has 19 exons, from which exons 7 and 8 can be alternatively spliced in neurons resulting in the formation of three major isoforms: APP695, APP751 and APP770 (Beyreuther et al., 1993; Tanaka et al., 1992; Rockenstein et al., 1995; Thakur and Mani, 2005). In APP751 exon 8 is skipped, whereas APP695 lacks both exons 7 and 8. Exon 7 encodes the domain of Kunitz-type serine protease inhibitor (KPI), whereas exon 8 codes for the OX-2 domain which is homologous to the MRC OX-2 antigen present on the surface of neurons and immune cells. Consequently, APP770 possesses both of these domains. APP751 has the KPI but lacks the OX-2 domain, whereas APP695 is devoid of both domains (Tanaka et al., 1992; Rockenstein et al., 1995; Thakur and Mani, 2005). APP695 is produced by neurons and is the most abundant in the brain. Brain levels of APP770 are generally low. The reason for the higher expression of APP695 and low levels of APP770 in the brain was found in the embryonic development. APP695 was expressed in neuroectodermal derivatives, whereas APP770 was restricted to mesodermal and endodermal derivatives (Sarasa et al., 2000). Brain aging is associated with a decline in APP695. In old mice mRNA levels of this isoform were lower than in adult animals. Furthermore, gonadectomy decreased APP695 mRNA levels in adult females, whereas estradiol supplementation reversed this effect (Thakur and Mani, 2005). In humans APP695 is the dominant isoform in younger individuals, whereas in the older subjects its levels are significantly reduced (Konig et al., 1989). In AD brain APP695 mRNA levels were diminished, whereas APP751 and APP770 were increased (Thakur and Mani, 2005; Barrachina et al., 2005; Rockenstein et al., 1995; Tanaka et al., 1992). It should be noted here that an age-related rise in APP770 and APP751 was also reported in non-AD subjects, but the ratio of the KPI-harboring (APP770+APP751) to KPI-lacking (APP695) isoforms increased more dramatically and earlier in the AD cases (Tanaka et al., 1992). The increase in APP isoforms with KPI domain was most prominent in the brain areas that are most severely affected by AD process, i.e., in the hippocampus and the nucleus basalis of Meynert and was proposed to be a possible origin of A β deposition (Rockenstein et al., 1995; Barrachina et al., 2005). This observation in AD brain was reinforced by similar data obtained in PDGF-hAPP transgenic mice, expressing AD pathology. The animals showed high levels of APP770 and APP751 and lower levels of APP695 mRNA (Rockenstein et al., 1995). On the other hand, a specific increase in APP695 mRNA was noted in brain regions involved in amyloid plaque formation (Jacobsen et al., 1991). This observation was explained by the fact that the deposition of A β in senile plaques is derived from APP695 lacking KPI and OX-2 domains (Thakur and Mani, 2005). Therefore, it was suggested that an imbalance in the protease inhibitor plays an important role in AD (Jacobsen et al., 1991) and that the deregulation of splicing of the exon 7 in brain aging is a putative risk factor for AD (Beyreuther et al., 1993). In addition to exons 7 and 8, exon 15 of the APP gene is also subject to alternative splicing. Omission of the exon 15 results in L-APP isoform with a functional recognition sequence for xylosyltransferase-mediated addition of glycosaminoglycans and proteoglycan formation (Sandbrink et al., 1997). In the brain it can be found in activated astrocytes and microglia. The absence or low levels of L-APP isoforms in neurons might be important for the susceptibility of the brain towards AD (Beyreuther et al., 1993; Sandbrink et al., 1997).

A β which is the main constituent of senile amyloid plaques is cleaved from APP by two proteolytic enzymes, the β - and γ -secretases (Hardy and Selkoe, 2002). The β -secretase is a transmembrane aspartyl-protease that is recognized as the β -site amyloid precursor protein-

cleaving enzyme 1 (BACE1). BACE1 first cleaves the APP at the N-terminus of the A β . This results in the formation of a 100 kDa soluble fragment and a 12kDa membrane anchored protein C99 at the C-terminus. The C99 is then cleaved by the γ -secretase producing the A β 40 and A β 42 species. Alterations in the balance between the β - and γ -secretases and their substrate APP were proposed to influence the development of AD (Zohar et al., 2005).

Alternative Splicing of Genes involved in A β Processing

BACE 1 (β -site APP Cleaving Enzyme 1)

BACE 1 activity and protein levels are significantly elevated in the brain of AD patients (Fukumoto et al., 2002). BACE1 overexpression increases the accumulation of A β in the brain, whereas BACE1 inhibitors reduce the A β formation (review in Annies et al., 2009). Deletion of the BACE1 gene in mice improves memory deficits and recovers neurodegeneration (Ohno et al., 2007). The BACE1 gene has nine exons that are translated into the full-length 501 amino acid active protein BACE1 501. The use of cryptic donor and acceptor sites in exons 3 and 4 generates in-frame deletions within the catalytic domain of BACE1 (Tanahashi and Tabira, 2001). Deletion of 75 bp inside exon 4 due to the alternative 3' splice site produces isoform BACE1 476 (the length of the protein is 476 amino acids compared to 501 amino acids in the full length protein). Deletion of 132bp inside exon 3 due to the alternative 5' splice site forms the isoform BACE1 457 (457 amino acids). Isoform BACE1 432 (432 amino acids) results from the use of both mentioned above alternative 5' and 3' splice sites in exons 3 and 4 (Tanahashi and Tabira, 2001). In vitro studies showed that enzymatic activity of BACE1 isoforms is dramatically decreased (Tanahashi and Tabira, 2001, Mowrer and Wolfe, 2008). Moreover, following co-expression of BACE1 476 and BACE1 457 with APP695 in HEK 293 cells, significant reduction in the secretion of A β 40 and A β 42 was noted (Tanahashi and Tabira, 2001). Furthermore, the use of antisense RNA oligos targeted against normal 5' and 3' BACE1 splice sites also showed substantial decrease in A β 40 production in HEK-swe cells (Mowrer and Wolfe, 2008). Although all of the known BACE1 isoforms were identified in different human brain regions, no data are available concerning possible changes in BACE1 alternative splicing in AD patients. At the moment there is only one study of BACE1 splice variants in tg2576 mice with the Swedish mutation of APP (Zohar et al., 2005). These mice develop age-dependent A β plaques and learning deficits. The ratio of BACE1 splice variants to the wild type BACE1 501 was diminished in different brain areas of tg2576 mice. This decrease was more pronounced for the BACE1 476 and BACE1 432 isoforms. In this animal model of AD the full length BACE1 with the highest enzymatic activity showed a huge, 2 to 4-fold dominance over the splice variants. On the contrary, in wild type animals the expression of BACE1 isoforms was even comparable to that of the full length BACE1 (BACE1 501 ~ BACE1 476) (Zohar et al., 2005). Together, these studies demonstrated that the increase in the levels of BACE1 splice variants with diminished enzymatic activity reduces A β production and is protective against AD development (figure 2). Thus, targeting of BACE1 normal splice sites with antisense RNA oligos or affecting factors that regulate BACE1 splicing may be promising therapeutic strategies in AD patients (Mowrer and Wolfe, 2008).

The γ -secretase complex responsible for the C-terminal cleavage of the APP consists of at least four proteins: presenilin, nicastrin, APH-1 (anterior pharynx defective) and PEN-2 (presenilin enhancer 2). Presenilin and APH-1 exist in two forms: presenilin 1 and 2, APH-1a

and APH-1b. APH-1a and APH-1b incorporate into different presenilin complexes. Moreover, APH-1a has two major splice variants APH-1aS and APH-1aL (Lee et al., 2002; Saito et al., 2005). Consequently, at least six types of the γ -secretase complex may be present depending on the type of presenilin and APH-1 inclusion and all of them were shown to have proteolytic activity (Shirotani et al., 2004).

Presenilins

Presenilins (PSs) represent a group of multi-pass transmembrane proteins that function as catalytic subunits of the γ -secretase intramembrane protease complex. In particular, PSs are required for the cleavage of the C-terminal fragment of the APP within the extracellular domain. PS-1 containing complexes have higher γ -secretase activity than those with PS-2. PSs gene mutations lead to an increase in the production of A β 42 that is the predominant compound accumulated in senile plaques. Like for the APP gene, mutations in the PS-1 and PS-2 genes were linked to familial (early-onset) autosomal dominant AD (Manabe et al., 2007; Suzuki et al., 2009).

Alternative splicing at the 3' end of exon 3 of PS-1 mRNA results in the appearance of the long form of PS-1 mRNA (VRSQ+) that contains four amino acids (VRSQ) and the short form VRSQ- that is devoid of this sequence (Isoe-Wada et al., 1999). In the brain of subjects with sporadic AD VRSQ+ isoform mRNA levels were reduced as compared to the control group. This alteration in exon 3 alternative splicing was brain-specific and was proposed to play a role in AD pathogenesis (Isoe-Wada et al., 1999).

Figure 2. Alternatively spliced transcripts may decrease A β secretion.

A splice donor site mutation in intron 4 of PS-1 is present in early-onset AD cases and is inherited in an autosomal dominant manner (De Jonghe et al., 1999). It produces 2 deletion isoforms (Δ 4 and Δ 4 cryptic) that form C-truncated PS-1 proteins (7kD) and one variant with an insert (insTAC) that is translated into a full-length PS-1 with one extra amino acid threonine between codons 113 and 114 (PS-1 T113-114ins). Following expression in vitro, these isoforms appeared to increase A β 42 production. Furthermore, the presence of the PS-1 T113-114ins was linked to the AD pathophysiology in intron 4 mutation carriers (De Jonghe et al., 1999). It should be noted that PS-1 splice variants are not necessarily related to AD pathology. For example Δ 8 isoform (lacking exon 8) was found not to influence A β production (Moriyama et al., 2000).

Concerning PS-2 two major splice variants associated with AD are known, i.e., PS2V and PS2 β . PS2V lacks exon 5 and encodes the N-terminal domain of the PS-2. It is translated into 14kDa deleterious protein with a novel C-terminus created by alternative splicing (Smith et al., 2004; Manabe et al., 2007; Sato et al., 1999, 2001). Exclusion of exon 5 during PS-2 mRNA processing is induced by hypoxia-mediated oxidant stress (Sato et al., 1999). This isoform is much more frequently expressed in the brain of sporadic AD cases. It was observed in 70% of AD and only 17.6% of control subjects (Sato et al., 1999; Manabe et al., 2007). PS2V protein levels were increased 2-fold in the frontal cortex of AD patients (Smith et al., 2004). Moreover, this isoform was found in neuropathologically affected neurons of the CA1 hippocampal subfield and temporal cortex of AD subjects. Furthermore, PS2V overexpression was shown to increase the production of A β 40 and A β 42 (Sato et al., 2001). Taken together, these data indicate that PS2V isoform contributes to neurodegeneration in AD (Sato et al., 2001; Smith et al., 2004).

PS2 β was so far cloned only in the mouse. This isoform results from small extension of the exon 9 of the PS-2 gene leading to the translation of four additional out-of-frame residues at the loop domain (Suzuki et al., 2009). As a consequence of these splicing events, PS2 β appeared to have the N-terminal part and a hydrophilic loop domain, but it lacked the seventh transmembrane domain and downstream C-terminal regions. PS2 β blocked formation of the γ -secretase complex in HEK293 cells by disturbing the interaction between nicastrin and APH-1 (anterior pharynx-defective phenotype 1). In this way it inhibited γ -secretase activity and reduced A β levels (Suzuki et al., 2009). Since the splicing sites of the PS2 β were conserved between mouse and human, it is plausible that this variant may be involved in the A β production in AD patients (figure 3). However, its expression in the AD brain remains to be elucidated.

Figure 3. Differential effect of PS-1 and PS-2 splice variants on A β 42 and A β 40 generation.

Nicastrin

Nicastrin maintains the stability of the γ -secretase complex and is important for its activation. Down-regulation of nicastrin expression by RNA-i leads to the decrease in the levels of other γ -secretase components, i.e., PS-1, APH-1 L and PEN-2 and, subsequently, to the reduction in A β secretion (Capell et al., 2003). Deletion of exon 16 (NCTN- Δ E16) of the nicastrin gene was identified in the human brain. In the hippocampus of APOE- ϵ 4 carriers this splice variant was observed more often in AD cases than in the non-AD group. It was, therefore, concluded that the presence of the NCTN- Δ E16 isoform may confer additional risk for the development of AD (Mitsuda et al., 2006). However, the difference in that study was not statistically significant, and it should also be pointed out that the comparison of AD subjects in this study was made with the non-AD group that included cases with Parkinson disease and

diffuse Lewy body disease. It is plausible that the exclusion of cases with neurological disorders would clarify the AD-related specificity of the NCTN- Δ E16 splice variant.

APH-1

APH-1 associates with nicastrin during early stage of γ -secretase complex assembly. This subcomplex of APH-1 and nicastrin further combines with PS and PEN-2 to form the mature γ -secretase. Two APH-1 genes are known in humans: APH-1a and APH-1b (Lee et al., 2002). APH-1a is believed to be more important for the γ -secretase assembly and activity than APH-1b (Shirotani et al., 2004). Down regulation of APH-1a, but not of APH-1b, results in altered maturation of nicastrin and decreased expression of PS-1, PS-2 and PEN-2 proteins (Lee et al., 2002; Shirotani et al., 2004; Saito and Araki, 2005). APH-1a has two alternatively spliced isoforms APH-1aS (247 amino acids) and APH-1aL (265 amino acids) that differ in C-terminal sequences. APH-1aS has exons 1 to 5 with a stop codon at the beginning of exon 6 (exon 6a). APH-1aL contains exons 1 to 5 and exon 6a with a stop codon in the last two thirds of the exon 6 (designated as exon 6b) (Lee et al., 2002). In human tissues expression of APH-1aS is 1.5 to 3 times higher than that of APH-1aL (Saito and Araki, 2005). This means that γ -secretase complex might include the APH-1aS isoform more often and that its pathogenic activity is rather related to this particular APH-1 splice variant.

APH-1b has a splice variant APH-1b Δ 4 lacking exon 4 that encodes the fourth transmembrane domain. It is characterized by the in-frame deletion of 123 nucleotides and is devoid of the conserved motif GXXXG that is important for the assembly with presenilins. APH-1b Δ 4 mRNA is expressed at low levels and is translated into unstable protein. Despite these caveats, APH-1b Δ 4 interacts with nicastrin in transfected HeLa cells (Saito et al., 2005). However, the relevance of this splice variant for the AD pathogenesis remains to be elucidated.

AIDA-1

Upon processing APP several fragments other than A β are released. One of them is short intracellular (cytoplasmic) domain (AID) that is formed following the γ -secretase proteolysis. It plays a role in apoptosis, calcium homeostasis and transcriptional regulation (Ghersi et al., 2004). AID interacts with many proteins that modulate its functions or interfere with APP processing and/or internalization. AIDA-1 (AID-associated protein 1) is the novel AID-binding protein that modulates A β processing. Several alternatively spliced variants of AIDA-1 are known from which only AIDA-1a binds to APP and diminishes A β secretion through the inhibition of γ -secretase (Ghersi et al., 2004). AIDA-1a is a truncated isoform that has exons 15 to 19 and then exons 21 to 27. It is lacking exons 1 to 14 and exon 20 (Δ 1-14, 20). AIDA-1a was shown to be present in the normal human brain but was absent in AD brain tissues (Ghersi et al., 2004). It is therefore, conceivable that a loss of AIDA-1a which is down regulating APP processing is an important step in AD pathogenesis (figure 2).

Clusterin

Clusterin, known as apolipoprotein J, attaches to A β peptides and inhibits their fibrillization. This protein is also needed for the clearance of A β peptides and fibrils by glial cells. Clusterin suppresses complement protein activation in AD (review in Nuutinen et al., 2009). Its expression is increased in the brain of AD cases, in particular in the hippocampus and entorhinal cortex. Clusterin immunoreactivity was observed in neuritic plaques, neuropil

threads and cerebrovascular amyloid deposits. However, it was rarely seen in diffuse amyloid plaques or neurons with neurofibrillary tangles (Giannokopoulos et al., 1998). It was proposed that the enhanced expression of clusterin in AD brain may rather be neuroprotective (Nuutinen et al., 2009). Deletion of exon 2 results in the appearance of the alternatively spliced variant that is translated into uncleaved and non-glycosylated protein with two nuclear localizing sequences. This $\Delta 2$ clusterin isoform translocates to the nucleus where it prevents the DNA repair and induces apoptosis through the interaction with Ku70 protein (Leskov et al., 2003). Although the significance of DNA damage and alterations in DNA repair in AD pathogenesis is well understood (Cotman and Su, 1996), the precise role of the nuclear clusterin lacking exon 2 in AD remains to be clarified.

FE65 Family Proteins

The FE65 family includes adaptor proteins FE65, FE65L1, FE65L2 that bind to the cytoplasmic domain of APP for its subsequent internalization. The FE65-APP complex is important for the modulation of the metabolism and functions of APP (Hu et al., 2002). In particular, FE65 binding to APP increases the proteolytic processing of the latter resulting in the augmented secretion of A β 40 and A β 42 (Sabo et al., 1999; Tanahashi and Tabira, 2002). Increased expression of FE65 mRNA in the cerebellar cortex and enhanced FE65 immunoreactivity in the CA4 hippocampal area were found in patients with very late onset of AD (Hu et al., 2000; Delatour et al., 2001). It was furthermore reported that carriers of the minor allele 2 of FE65 were resistant to the very low onset AD. This protective role was associated with a polymorphism in intron 13 that causes the appearance of the cryptic acceptor splicing site within the last exon 14 resulting in the alternatively spliced isoform FE65a2 with 55 amino acid deletion at the C-terminus (Hu et al., 2002). FE65a2 showed reduced binding to APP (Hu et al., 2002). Importantly, this observation demonstrates that preferential expression of the alternatively spliced isoform with attenuated functional properties may lead to the decreased risk of the very low onset AD.

Modulation of alternative splicing of FE65L1 mRNA by the non-coding RNA 45A in vitro results in the preferential generation of exon 8-containing isoforms “a” and “b” that have reduced ability to interact with APP. This causes a decrease in the secretion of β -amyloid but increases the ratio of A β 42/A β 40 ratio providing favourable conditions for A β aggregation (Penna et al., 2013).

Alternative splicing of the FE65L2mRNA generates nuclear isoforms I-214 and I-245 lacking phosphotyrosine-interaction domain (PID) 2 that is necessary for the interaction with APP. Both of them also have alterations within PID1. I-214 isoform (214 amino acid length) is produced by the use of alternative donor splice site in exon 6 and alternative acceptor site in intron 6. These splicing events cause the deletion of 66 amino acids with the appearance of unique 19 amino acids at the C-terminus. Increased ratio of I-214 to canonical FE65L2 was associated with augmented apoptosis in vitro. Moreover, in contrast to the full length FE65L2, I-214 did not influence secretion of A β 40 and A β 42 (Tanahashi and Tabira, 2002). This finding shows that overexpression of the alternatively spliced isoform I-214 may not be simply regarded as positive or negative with respect to its possible role in AD pathogenesis. On one hand I-214 is pro-apoptotic but at the same time it may be protective against A β species.

Apolipoprotein E (APOE)

APOE is considered to be important for the regional vulnerability of neurons in AD (Xu et al., 1999). Moreover, APOE participates in the clearance of A β , protection against A β neurotoxicity, stabilization of microtubules and neuronal repair in a receptor-mediated way (Clatworthy et al., 1999). APOE gene has several alleles, from which the e4 is associated with increased risk and earlier onset of AD possibly because it is accompanied by diminished neuronal activity (Dubelaar et al., 2004), e3 is regarded as neutral, whereas e2 is protective against AD. By means of RNA Seq three isoforms of the APOE gene originating from different transcription sites were identified in the temporal lobe of control and AD patients with APOE e3 genotype. Splice variants APOE 001 and 002 contained all 4 exons and were transcribed from promoter TSS A. APOE 005 was devoid of the first exon since it was generated by an alternative promoter TSS B upstream of the second exon (Twine et al., 2011). In AD cases APOE 001 and 002 were diminished. This decrease was much more pronounced for the APOE 002 isoform that was specific to the temporal cortex. On the contrary, APOE 005 was significantly increased in AD subjects. Accordingly, TSS A promoter was 3-fold down-regulated and TSS B was 26.5-fold up-regulated in the AD group (Twine et al., 2011). Interestingly, differential expression of the APOE isoforms and promoter use with regards to AD was noted in this study only in the temporal cortex and not in the total brain samples. Therefore, it is plausible that alterations in the APOE gene splicing pattern are related to AD neuropathology. The precise role of the APOE splice variants in AD remains to be elucidated.

Alternative Splicing of Other Candidate Genes

Acetylcholinesterase

AD is associated with a pronounced cholinergic deficit resulting from the loss and decreased metabolic activity of cholinergic neurons. These alterations are directly related to learning and memory problems in AD patients (Cummings and Back, 1998; Swaab, 2004). A link between cholinergic dysfunction and amyloid neuropathology is present in the 3' alternative splicing of the acetylcholinesterase (AChE) gene that generates C-terminal isoforms with opposed effects on amyloid fibril deposition (Inestrosa et al., 1996; Berson et al., 2008). In the synaptic AChE-S variant, that is the major transcript in the brain, exon 5 is deleted. The second most common isoform AChE-R (the "readthrough" form) contains a pseudo-intron 4 (I4) between exons 4 and 5 (Grisaru et al., 1999). In vitro, AChE-S increases A β fibril formation and enhances their neurotoxic effects (Inestrosa et al., 1996; Berson et al., 2008). AChE-R appeared to act as an antagonist of AChE-S since it reduced the formation of insoluble A β oligomers and fibrils and abolished A β toxicity to SH-SY5Y cells in a dose-dependent manner (Berson et al., 2008). In double transgenic APPsw/AChE-R mice cortical amyloid plaque accumulation was reduced as compared to single APPsw mice. In AD patients AChE-R protein was decreased in hippocampal neurons. Although, AChE-R mRNA was up-regulated in the same brain region of AD cases, both AChE-R mRNA and protein appeared to be less stable than those of AChE-S variant. It was, therefore, concluded that despite protective direction of 3' alternative splicing of AChE pre-mRNA in AD brain, the protein of the favorable AChE-R isoform may undergo enhanced proteolysis (Berson et al., 2008). It is of particular interest that cholinesterase inhibitors that are used as symptomatic treatment for AD, show differential

effects on the CSF protein levels of AChE-R and AChE-S. In AD patients treated for a year rivastigmine selectively up-regulated the AChE-R, while tacrine increased both AChE-R and AChE-S isoforms. In untreated subjects after 1 year follow-up AChE-R levels diminished while AChE-S concentrations raised. These changes were accompanied by declined MMSE scores (Darreh-Shori et al., 2004). To this end the data indicate that an increase in the neuroprotective AChE-R isoform may be beneficial in the course and treatment of AD.

Tissue Transglutaminase

Tissue transglutaminase (TGase2 or tTG) is the most common member of the transglutaminase family. It has GTP-ase activity, binds both GTP and ATP and is involved in the regulation of signal transduction. Moreover, tTG mediates protein crosslinking and, therefore, is implicated in the pathogenesis of neurodegenerative disorders with excessive protein aggregation (Citron et al., 2002). In AD both tTG enzymatic activity and gene expression are elevated (Kim et al., 1999; Citron et al., 2001; Citron et al., 2002). Furthermore, tTG crosslinks APP and A β , binds to tau and colocalizes with both amyloid plaques and neurofibrillary tangles (Ikura et al., 1993; Ho et al., 1994; Zhang et al., 1998; Citron et al., 2001). Alternative splicing of the tTG pre-mRNA may result in the appearance of long (L) and short (S) variants. Short isoforms lack the GTP-binding domain and are more active in protein crosslinking. In the brain of non-demented subjects only long forms of the tTG were present. In AD brain samples both L and S isoforms were observed suggesting that neurodegenerative events promote tTG alternative splicing (Citron et al., 2001). Moreover, the selective presence of the S tTG variant with unregulated crosslinking only in AD cases indicates that this isoform is largely involved in tau and amyloid neuropathology. This observation further establishes an important link between the AD pathogenesis and alternative splicing of the tTG mRNA.

Estrogen Receptor α

Menopause-related loss of estrogens in women is an important risk factor for AD (Naftolin and Malaspina, 2007; Barron and Pike, 2012). Consistent with this, women have a higher risk for developing AD than men (Craig and Murphy, 2008). Although not without controversy, estrogen therapy initiated during perimenopause within the "critical window" can improve cognitive functions and reduce the risk of dementia (Brinton, 2005; Zandi et al., 2002; Craig and Murphy, 2008). Estrogens mediate their effects mainly via two types of cognate receptors: ER α and ER β . The survey of the literature shows that targeting ER α may offer promising alternative to estrogen therapy to protect cognitive functions in menopausal women (Bailey et al., 2011). In our own studies we found that in AD nuclear expression of ER α is elevated in the neurons of the hypothalamus and basal forebrain involved in the regulation of memory, but was decreased in the hippocampus (Ishunina and Swaab, 2001; Ishunina et al., 2003; Ishunina et al., 2007). Since a lot of changes in the alternatively spliced isoforms are intimately linked to AD (splice variants within plaques, splice variants of enzymes involved in A β processing, i.e., BACE, splice forms of acetylcholinesterase and their selective changes under different cholinesterase inhibitors, (see above)), the idea that the sensitivity to estrogen treatment may be related to ER splice variants was further explored. Investigation of the alternative splicing of the ER α mRNA in different brain areas showed that both the number of ER α splice variants per brain area and mRNA levels of the most common ER α splice forms lacking exon 7 or 2 were significantly diminished in AD cases compared to the non-demented control group. These alterations were more pronounced in AD women than in AD men. Among

numerous ER α isoforms deletion of the exon 7 ($\Delta 7$) appeared to be the most ubiquitous in the human brain (Ishunina and Swaab, 2012). This is a dominant negative variant lacking a substantial portion of the ligand binding domain. Consequently, $\Delta 7$ has minor ability to bind estrogens. Its capacity to bind DNA is also reduced (Bollig and Mikcisek, 2000; Garcia-Pedrero et al., 2003). Nevertheless, $\Delta 7$ may form heterodimers with both canonical ER α and ER β and in this way it significantly suppresses estrogen signaling in different cell types (Garcia-Pedrero et al., 2003; Wong and Weickert, 2009). The percentage of brain areas where $\Delta 7$ was observed as a single form of ER α was nonsignificantly larger in AD (29%) than in control (16%) cases. Moreover, the frequency of complex ER α splice variants with large deletions due to alternative 5' and 3' splice sites inside exons was higher in AD than in control women (Ishunina and Swaab, 2012). With the help of antibodies recognizing specific splice sites of one of the novel ER α splice variants TADDI that we identified in the human hippocampus we further assessed its protein expression in the brain of AD cases. In this isoform 31 bp are deleted from the junction between exons 3 and 4, and 13 nucleotides from exon 2 are inserted into this splice site (Ishunina et al., 2007). In HeLa cells TADDI was dominant negative since it significantly suppressed transcriptional activity of the wtER α (wild type or canonical ER α). However, in dopaminergic M17 cells this splice variant was clearly dominant positive. Its own transcriptional activity was higher than that of the wtER α . Following co-expression with wtER α , estradiol-stimulated transcriptional activity augmented profoundly to the level of TADDI+ wtER α (Ishunina et al., 2013). Immunocytochemical expression of TADDI was clearly decreased in the hippocampus, nucleus basalis of Meynert and hypothalamic tuberomammillary and supraoptic nuclei of AD female subjects compared to control women (Ishunina and Swaab, 2009). Together, these data show that alternative splicing of the ER α mRNA is down-regulated in AD and more significantly in female than in male patients. At the same time, molecular defects in ER α mRNA variants are more severe in AD women than in the female cases of the control group.

Brain Derived Neurotrophic Factor (BDNF)

BDNF promotes survival, metabolic activity, synaptic transmission and excitatory properties of the hippocampal, cortical and basal forebrain cholinergic neurons (reviewed by Garzon et al., 2002). The loss of function and synaptic connectivity of these neurons in AD brain was attributed to the decline in BDNF. Indeed, both mRNA and protein levels of BDNF were significantly decreased in the hippocampus and cortex of AD patients (Phillips et al., 1991; Holsinger et al., 2000; Connor et al., 1997; Hock et al., 2000). Alternative splicing of 6 upstream non-coding exons to the single coding exon 5 produces at least 7 transcripts designates as 1 (exon 1 spliced to exon 5), 2 (exon 2 joined with exon 5), 3 (exon 3 spliced to exon 5), 4 (exon 4 connected to exon 5), 4I (exon 4I joined with exon 5), 4Ia (sequence inside exon 4I spliced to exon 5), 5U (exon 5U joined with exon 5) (Aoyama et al., 2001; Garzon et al., 2002). Splice variants 1, 2 and 3 were significantly down-regulated in the parietal cortex of AD patients, while other isoforms were not changed (Garzon et al., 2002). These data point to the dysregulation of alternative splicing of the BDNF mRNA that may contribute to neurotrophic imbalances in the AD brain.

Tropomyosin Receptor Kinase B (TrkB)

The neurotrophic effects of BDNF are mediated by the tropomyosin receptor kinase B (TrkB) (Patapoutian and Reichardt, 2001). The full-length TrkB-TK⁺ (with intracellular

tyrosine kinase domain (TK+)) is encoded by 24 exons and is expressed primarily in neurons. Two C-terminal truncated isoforms, i.e., TrkB-TK- and TrkB-Shc, are generated by alternative splicing and lack the tyrosine kinase domain. TrkB-TK- is encoded by 16 exons. TrkB-Shc includes exon 19 with associated premature stop codon that is absent in the full-length TrkB-TK+. TrkB-Shc is mainly confined to neurons, whereas TrkB-TK- to glial cells. Both isoforms can dimerize with TrkB-TK+ and function as dominant negative splice variants that reduce neurotrophin signaling (Stoilov et al., 2002; Wong et al., 2012). TrkB-Shc mRNA and protein expression were markedly elevated in the hippocampus of AD cases, whereas the levels of either TrkB-TK+ or TrkB-TK- were not changed. Furthermore, TrkB-Shc appeared to colocalize with TrkB-TK+ and suppressed the BDNF/TrkB-TK+ signaling via the mitogen-activated protein kinase (MEK). Interestingly, the levels of TrkB-Shc mRNA in differentiated neuronal SHSY5Y cells were increased in the presence of fibrillar A β 42 (Wong et al., 2012). Given that overexpression of TrkB-Shc may decrease APP intracellular domain-mediated transcription that is known to promote apoptosis and to contribute to the A β 42 toxicity (Ansaloni et al., 2011; Wong et al., 2012), the reported up-regulation of TrkB-Shc in AD hippocampal neurons may represent a compensatory response and may promote neuronal survival (Wong et al., 2012).

Excitatory Amino Acid Transporter 2 (EAAT2)

Preferential degeneration of glutamatergic neurons in AD leads to an early glutamatergic deficit that is apparent before cognitive decline. Glutamate transport is decreased in the cortex of AD cases (Bert and O'Shea, 2007). This may result in the increased accumulation of glutamate in synaptic clefts and further overstimulation of postsynaptic glutamate receptors causing neuronal loss via excitotoxicity (Masliah et al., 1996). Moreover, cortical neurons receiving glutamatergic projections represent the preferred location of neurofibrillary tangles (Francis, 2003). Glutamate transport is mediated by excitatory amino acid transporters (EAAT) from which the major glial type EAAT2 was related to the decreased glutamate uptake in AD brain tissues. EAAT2 mRNA was down-regulated in the hippocampus and various cortical areas of AD cases (Li et al., 1997; Scott et al., 2011). EAAT2 immunoreactivity was diminished in the AD frontal cortex (Li et al., 1997). Furthermore, EAAT2 was found to co-localize with hyperphosphorylated tau protein in dystrophic neurons (Thal, 2002). Two exon-skipping splice variants of the EAAT2 mRNA lacking exons 7 (EAAT Δ 7) and 9 (EAAT2 Δ 9) were increased in the cerebral cortex of AD patients and showed positive correlation with pathological severity. These isoforms are unable to transport glutamate themselves and suppress glutamate transport capacity of the wtEAAT2 (Scott et al., 2011). Consequently, higher expression of dominant negative EAAT2 splice variants EAAT Δ 7 and EAAT2 Δ 9 suggests their significant contribution to the reduced glutamate transport and increased neuronal death by excitotoxicity in the brain of AD cases. Identification of the EAAT2 Δ 9 protein in dystrophic neuritis and glial cell processes in the vicinity of amyloid plaques in AD brain further supports the role of EAAT2 isoforms in neurodegeneration (Pow and Cook, 2009).

Ion Channels

Alterations in the function of ion channels, like glutamate receptors, nicotinic cholinergic receptors, calcium and potassium channels, have been clearly related to AD pathophysiology. Moreover, AD-associated neurodegeneration was partially linked to the overactivation of N-methyl-D-aspartate receptor followed by the increase in intracellular calcium and oxidative

stress (Heinzen et al., 2007; Hynd et al., 2004). The splice variant microarray showed that 12% of the ion channel genes are alternatively spliced in AD (Heinzen et al., 2007). These changes are briefly summarized in the following table.

Thus, approximately equal proportions of the ion channel genes demonstrate up- or down-regulated alternative splicing in AD. Although the precise role of these changes remains to be elucidated, the data are in agreement with the general idea of this chapter that alternative splicing is dysregulated in AD.

Table 1. Ion channel genes with increased or decreased alternative splicing

Ion channel genes	The number of genes with increased alternative splicing	The number of genes with decreased alternative splicing
Ca ²⁺ channels	2	4
Chloride channels		4
Sodium channels		3
Potassium channels	9	5
GABA receptors	2	1
Ionotropic glutamate receptors	1	2
Two pore segment channels	1	
mucolipin	2	
Ryanodine receptors	2	

Synapsin

Synaptic pathology plays an extremely important role in the pathophysiology of AD since the number of synapses decreases in the AD brain and because A β oligomers bind to synapses involving the latter into the fine structure of senile plaques. Certain synaptic markers, i.e., synapsins and synaptophysin, were reported to be decreased in AD reflecting these synaptic alterations (Duyckaerts et al., 2009). Synapsins represent a group of phosphoproteins that regulate the number of synaptic vesicles available for neurotransmitters (Greengard et al., 1993). Synapsin II is associated with excitatory synapses, whereas synapsin I – with inhibitory ones (Mandell et al., 1992). Synapsin II has two isoforms generated by alternative splicing: synapsin IIa and synapsin IIb. Synapsin IIa is implicated in synaptic plasticity and neurotransmitter release. It has splice variants Ia, IIa, IIIa (I-III) that were all selectively decreased in the entorhinal, but not the in visual cortex of cases with the earliest clinically detectable stages of AD (Ho et al., 2001). Because there was no change in the expression of IIb isoform, it seems reasonable to conclude that these data point again to the dysregulation of alternative splicing in AD. Diminished levels of the synapsin IIa variants were associated with the early phase of AD cognitive decline and were proposed to be useful in the development of novel strategies in the treatment of early AD (Ho et al., 2001).

Regulator of Calcineurin (RCAN1)

RCAN1 might well be implicated in the pathogenesis of AD since it prevents dephosphorylation of the tau protein by calcineurin. This results in the accumulation of

hyperphosphorylated tau and subsequent formation of paired helical filaments and neurofibrillary tangles (Ermak et al., 2001). Consistent with this functional role, RCAN1 gene expression was markedly enhanced in the brain areas of AD patients with pronounced neuropathological changes (Ermak et al., 2001; Harris et al., 2007). Three RCAN1 isoforms generated by alternative splicing are present in the human brain at both the mRNA and protein levels: RCAN1-1L, RCAN1-1S and RCAN1-4. They have the same C-terminus encoded by exons 5, 6 and 7 and differ in the first exon. RCAN1-1L ("Long") contains 55 N-terminal amino acids encoded by exon 1 that are directly spliced to 168 amino acids encoded by exons 5, 6 and 7 (1-5,6,7). RCAN1-1S ("Short") has 29 N-terminal amino acids coded by a part of the exon 1 that are similarly joined to the same C-terminal 168aa (1*-5,6,7). RCAN1-4 does not have the first exon. Its first 29aa are encoded by exon 4 followed by the common C-terminus generated by exons 5, 6 and 7 (4,5,6,7) (Harris et al., 2007). RCAN1-1L is the most abundant isoform in the human brain. It is selectively restricted to neurons and not to glial cells. Moreover, RCAN1-1L mRNA and protein levels were significantly elevated in the brain of AD cases and, in particular, in the brain regions most severely affected by AD neuropathology (i.e., the hippocampus and cerebral cortex) (Harris et al., 2007). These data point to an important functional role of RCAN1-1L splice variant in the formation of neurofibrillary tangles and pathogenesis of AD.

Glial Fibrillar Acidic Protein (GFAP)

GFAP is widely considered as a marker of astrocytes. However, there is clear evidence that this glial protein may appear in the hippocampal neurons of AD patients as a result of alternative splicing alterations. Neuronal GFAP is encoded by two out-of frame splice variants $\Delta 6$ (lacking exon 6) and $\Delta 164$ nt (with 164 nucleotides deletion from exon 6 and 5' portion of the exon 7 due to cryptic donor and acceptor splice sites inside exons 6 and 7). Their translation results in the formation of aberrant GFAP+1 proteins with the out-of-frame C-termini. These isoforms were associated with AD neuropathology since they were present in AD hippocampal neurons and were very rarely observed in the non-demented subjects (Hol et al., 2003). Generation of these mutant proteins was proposed to be due to the initiation of GFAP gene expression in AD neurons with concomitant failure of the proteasomal degradation machinery (Hol et al., 2003).

Ubiquilin-1

Proteasomal disfunction is an important pathological hallmark of AD. It was shown that alternative splicing of the proteins involved in the proteasomal machinery, for example ubiquilin-1, may be affected in AD. Ubiquilin-1 interacts with the proteasome and ubiquitin ligases and is involved in the regulation of protein degradation. In addition, with the help of the C-terminal ubiquitin-associated domain ubiquilin-1 interacts with both PS-1 and PS-2 promoting presenilin accumulation (Mah et al., 2000; Bertram et al., 2005). Therefore, ubiquilin-1 is considered as one of the candidate genes for AD. It has two main transcript variants that are designated as TV1 and TV2. TV1 has 11 exons. In TV2 exon 8 is deleted ($\Delta 8$) as a result of intronic single-nucleotide polymorphism located downstream of exon 8. This polymorphism in turn was linked to the risk allele UBQ-8i on chromosome 9q22. Carriers of one or two copies of the UBQ-8i showed a significant and dose-dependent increase in the risk of AD. In AD patients who have significantly increased frequency of the UBQ-8i allele, the ratio of TV2/TV1 isoforms was elevated (Bertram et al., 2005). Thus, alterations in alternative splicing of ubiquilin-1 mRNA in AD patients lead to the increased expression of the TV2

isoform lacking exon 8 and are associated with the single nucleotide polymorphism in the UBQ-8i risk allele. Since exon 8 encodes a part of the C-terminal domain for the interaction with protein-disulfide isomerase, certain aspects of protein degradation in the proteasome as well as interaction with PS-1 and PS-2 may be altered in AD patients carrying the UBQ-8i risk allele.

CDKN1A Interacting Zinc Finger Protein 1 (CIZ1)

CIZ1 is the DNA replication factor that regulates entry in the S-phase. Inappropriate re-entry of post-mitotic neurons into the cell cycle may alter their function in AD (Nagy, 2000). In-frame deletion of 168 nucleotides from the central portion of the CIZ1 exon 8 generates alternatively spliced isoform CIZ1S lacking 56 amino acids in the second glutamine-rich domain. In the hippocampus of AD cases CIZ1S mRNA was 2.5-fold up-regulated and was expressed at levels comparable with those for canonical CIZ1 mRNA (Mackeprang Dahmcke et al., 2008). These data suggested that increased expression of CIZ1S may contribute to alterations in the regulation of the cell cycle in AD.

Differentially Expressed in Normal and Neoplastic Tissues MAPK-Activating, Death Domain Protein (DENN/MADD)

Splice variants of the DENN/MADD are involved in the cell survival. One of them, IG20 (insulinoma-glucagonoma clone 20) is pro-apoptotic, whereas another one, the DM-SV, has opposing anti-apoptotic function. Knockdown of all of these variants results in apoptosis and tumor shrinkage (Efimova et al., 2004; Lim and Chow, 2002; Mo et al., 2012). In the central nervous system IG20 may be involved in synaptic vesicle cycling (Niwa et al., 2008), whereas the DM-SV was increased in Purkinje cells of the cerebellum following acute hypoxia (Zhang et al., 1998). In the hippocampus of advanced AD cases total DMI (DENN/MADD/IG20) complex is diminished (Del Villar and Millar, 2004). In SH-SY5Y cells oligomeric A β alter the ratio of DMI splice variants DM-SV/IG20 in a time-dependent manner. During first hours of exposure to A β this ratio increases and then after 24 hours becomes reversed. In vitro results are in concordance with the data in postmortem brain tissues. In the nucleus basalis of Meynert and the hippocampus of patients with mild cognitive impairment the ratio DM-SV/IG20 was increased, whereas in the hippocampus of cases with advanced AD the ratio was reversed (Mo et al., 2012). Thus, the peak in DM-SV/IG20 might be protective to A β . However, it decreases during further gradual A β accumulation. It was, therefore, concluded that the DM-SV might be protective against A β neurotoxicity and might reduce the cell death, whereas the IG20 may contribute to selective neuronal vulnerability in AD (Mo et al., 2012).

Diazepam-Binding Inhibitor (DBI)

The DBI is an acyl-CoA binding protein that is involved in fatty acid metabolism and steroidogenesis. It is also implicated in inflammation and apoptosis (Zavala, 1997; Mills et al., 2013). The DBI gene was stimulated by A β in cultured astrocytes (Tokay et al., 2008) and was 3-fold up-regulated in the parietal cortex of AD patients (Mills et al., 2013). Three alternatively spliced isoforms of DBI were identified: DBI-003, DBI-008, DBI-009. DBI-003 is a protein – coding isoform with 4 exons generated by the use of the TSS-B promoter. DBI-008 and DBI-009 are non-coding variants controlled by the different promoter TSS-A. DBI-008 has 3 exons and keeps intronic sequences at the 5' termini of the first and third exons. DBI-009 contains 2

exons with retained introns. DBI-009 was 30-fold increased, DBI-003 was dramatically down-regulated and DBI-008 was not changed in the parietal cortex of AD patients (Mills et al., 2013). Based on experimental evidence (reviewed in Mills et al., 2013) it can be suggested that enhanced expression of the non-coding intron-bearing isoform DBI-009 may affect firing properties of neurons and may be implicated in inflammatory processes in which astrocytes are involved. However, the precise role of the DBI-009 variant in AD pathogenesis remains to be elucidated.

CONCLUSION

This chapter reveals two major ideas concerning alternative splicing in AD. First of all, alternative splicing in the AD affected brain areas is dysregulated. Some genes show increased alternative splicing, others diminished. Certain isoforms of the same mRNA can be elevated, others did not change or even decreased. These data lead to the conclusion that AD is a disease characterized by dysregulated splicing. In support of this idea, Illumina RNA-Seq analysis revealed elevated transcriptome activity in the parietal cortex of AD patients and showed that 4073 alternatively spliced isoforms were up-regulated while 558 were down-regulated (Mills et al., 2013). Misregulation of alternative splicing in AD may result from mutations in the genes themselves or alterations in the regulators of splicing. Mitochondrial damage and the related hypoxic stress are important factors influencing alternative splicing changes in AD (Maracchioni et al., 2007). Second, the extent and severity of molecular defects in alternatively spliced isoforms is generally greater in AD patients. Very often unexpected (“cryptic”) splice sites are present inside classical exons or even within the introns. Together, the data show that alternative splicing and its regulators may be attractive targets for the development of novel treatment options for AD.

Chapter 20

PLANT RNA-BINDING PROTEINS IMPLICATE MRNA PROCESSING IN ABSCISIC ACID (ABA) RESPONSES

Raquel F. Carvalho, Vera S. Nunes and Paula Duque*

Instituto Gulbenkian de Ciência, Oeiras, Portugal

ABSTRACT

Posttranscriptional control of gene expression is crucial for biological processes. In particular, alternative splicing allows the same gene to produce multiple proteins and is thus a key generator of functional complexity. This posttranscriptional regulatory mechanism is a prevalent feature of eukaryotic genomes, being currently estimated to occur in over 50% of plant genes. RNA-binding proteins (RBPs) are known to control many aspects of RNA metabolism, from pre-mRNA splicing to the transport and stability of mRNA transcripts. The Arabidopsis and rice genomes contain about 200-250 genes predicted to encode RBPs, but few of these proteins have been characterized in plants.

As sessile organisms, plants are continuously exposed to environmental challenges that affect their growth and development. The phytohormone abscisic acid (ABA) is crucial in the coordination of plant responses to various abiotic stress factors. Interestingly, several RNA-metabolism genes have recently been implicated in the ABA pathway, providing a link between mRNA processing and ABA-mediated plant stress responses. Indeed, the loss- or gain-of-function of genes encoding different classes of RBPs directly involved in constitutive and alternative pre-mRNA splicing, such as snRNP factors or SR and hnRNP proteins, has been shown to result in striking ABA-response plant phenotypes. Functional roles in ABA biosynthesis or signaling have also been reported for other RBPs, including cap-binding proteins, RNA helicases, pentatricopeptide repeat proteins or poly(A) processing enzymes. Taken together, these data support the notion that posttranscriptional networks act as central coordinators of plant stress responses, namely by targeting key components of ABA signal transduction machinery. Future identification of the direct targets of these RBPs should uncover the molecular mechanisms underlying the mode of action of these proteins in the regulation of the ABA pathway.

1. INTRODUCTION

The regulation of gene expression is of crucial importance for biological processes in all living organisms. It can be modulated at different steps, from transcriptional initiation to mRNA processing and from there to the post-translational modification of a protein. Post-transcriptional gene regulation in eukaryotes involves several processes, including precursor-mRNA (pre-mRNA) splicing, capping and polyadenylation, or nucleocytoplasmic transport, stabilization and degradation of mRNA. RNA-binding proteins (RBPs) interact with single/double stranded RNA molecules in order to regulate these different cellular processes. Several RNA-binding motifs have been identified (reviewed in Burd and Dreyfuss, 1994; Lunde et al., 2007), with the most widely spread being the RNA-Recognition motif (RRM) followed by the K homology (KH) domain. Other RNA-binding motifs include glycine-rich, arginine-rich and RNA-binding domains, as well as zinc-fingers, DEAD boxes and RGG-boxes. The Arabidopsis genome contains more than 200 genes predicted to encode RBPs (Lorkovic and Barta, 2002; Lorkovic, 2009), whereas about 250 RBP genes have been identified in rice (Cook et al., 2010).

RNA splicing is the process that removes the noncoding introns from the pre-mRNA and joins the coding exons in order to obtain a mature functional mRNA that can later be translated into a protein. The splicing reaction is carried out by a large protein complex, the spliceosome, composed by five small nuclear ribonucleoproteins (snRNPs) and a large number of non-snRNP proteins. The efficient excision of introns from the pre-mRNA relies on specific consensus sequences such as splice sites located at the intron/exon junctions. However, these sequences are short and degenerate and usually not sufficient to determine the assembly of a functional spliceosome. Additional sequence information as well as protein interactions are necessary to activate their use. Indeed, apart from splice sites, other *cis*-elements within exons and introns are essential for the accuracy of splice site selection. These regulatory sequences, called exonic or intronic splicing enhancers (ESEs or ISEs) and silencers (ESSs or ISSs), are bound and activated by one or more of several related splicing factors, thus determining the strength of nearby splice sites.

Alternative splicing occurs when splice sites are differentially recognized, thus allowing for different rearrangements of a gene's coding fragments and generating multiple forms of mature mRNA from the same pre-mRNA molecule. In this way, a single gene may lead to the production of more than one polypeptide, greatly upscaling the genome coding capacity and providing a versatile means of regulating gene expression. In animals, alternative splicing has been found to determine such diverse biological processes as gender specification in *Drosophila* (Bell et al., 1991) or sound frequency recognition in the avian cochlea (Ramanathan et al., 1999) and in humans it is well known that its misregulation can lead to many important diseases (reviewed in Blencowe, 2006; Ward and Cooper, 2010). In fact, splice-site choice must be tightly regulated in time and space. Because splicing factors bind to numerous weakly conserved sequences, a single protein can regulate multiple target genes. In animal systems, a small number of proteins has been repeatedly found to be responsible for the regulation of a large number of alternative splicing events, and most known regulators of alternative splicing are ubiquitously expressed instead of tissue-specific (reviewed in Stamm et al., 2005; Nilsen and Graveley, 2010).

In the last decade great advances have been made regarding the analysis of alternative splicing, especially in plants, where studies were limited to individual genes. The most recent estimates, based on next-generation sequencing, indicate that at least 61% of the intron-containing genes in *Arabidopsis* (Marquez et al., 2012) as well as 48% and 55% of the rice (Lu et al., 2010) and barley (International Barley Genome Sequencing et al., 2012) genomes, respectively, are alternatively spliced. These figures are still lower than in humans, where 95% of the multi-exon genes are predicted to undergo alternative splicing (Pan et al., 2008; Wang et al., 2008), but are most likely to increase as more plant RNA-sequence data become available, particularly from various tissues, cell types and developmental stages or from plants grown under different environmental conditions.

Stress in plants can be defined as any external factor exerting a negative impact on their survival, growth or development. As sessile organisms, plants are continuously exposed to unfavourable environments that result in some degree of stress. The strategies they employ to respond to these adverse conditions can be highly complex, involving changes at the transcriptome, cellular and physiological levels. The phytohormone abscisic acid (ABA) plays key regulatory roles in many plant biological processes, from embryo maturation, seed development and germination to root growth, leaf abscission, fruit ripening and the regulation of stomatal apertures. Importantly, ABA action not only involves developmental and physiological regulation but is also crucial in the coordination of various stress signal transduction pathways, with a wide variety of abiotic factors, such as drought, desiccation, high salinity and cold or heat stress being known to trigger an increase in endogenous ABA levels (reviewed in Tuteja, 2007; Hong et al., 2013). Furthermore, genetic screens based on seed germination or on the use of reporter gene systems have allowed the isolation of a myriad of mutants affected in ABA responses.

In recent years, many RNA-metabolism genes have been described as components of ABA signaling pathways, strongly suggesting that posttranscriptional networks act as central coordinators of plant abiotic stress responses by targeting, for example, key components of the ABA signal transduction machinery. This chapter will review the available functional evidence linking splicing factors and other RBPs to the regulation of plant ABA stress responses (Table 1).

2. SPLICING FACTORS

2.1. snRNP Factors

snRNPs are found in the nucleus of eukaryotic cells and consist of one small RNA molecule (snRNA), a core of seven Sm proteins, which form a ring structure with a hole in the middle through which a U-rich sequence in the snRNA passes, and additional snRNP-specific proteins (reviewed in Valadkhan and Jaladat, 2010). An exception occurs for the U6 snRNA, which lacks an Sm site and therefore formation of the corresponding U6 snRNP involves the association of seven so-called Sm-like proteins (LSm). LSm proteins are structurally related to Sm proteins and modulate various aspects of RNA metabolism including splicing, nuclear export and degradation (Salgado-Garrido et al., 1999; reviewed in He and Parker, 2000; Valadkhan and Jaladat, 2010). In mammals and yeast, the LSm2-LSm8 heptameric complex

functions in U6 snRNP biogenesis for pre-mRNA splicing and therefore associates directly or indirectly with several splicing factors, whereas the LSM1-LSM7 complex has a role in mRNA degradation through decapping of mRNAs, leading to 5' to 3' exonucleolytic cleavage (Achsel et al., 1999; Bouveret et al., 2000; reviewed in He and Parker, 2000). Molecular and functional analyses of the Arabidopsis LSM gene family has shown that plant LSM proteins, similarly to those in yeast and animals, are organized in two different heptameric complexes, being essential for the correct turnover and splicing of selected development-related mRNAs and thus for normal Arabidopsis development (Perea-Resa et al., 2012).

In a genomewide gene expression study, Hoth et al. (2002) identified more than one thousand ABA-responsive genes, including novel ABA targets. More detailed analyses revealed several of these ABA-regulated genes to encode snRNP proteins, with Sm core genes as well as U5 and U4/U6 snRNP-specific protein genes being highly represented (Raab and Hoth, 2007). Among these genes, *AtPRP4/AtSAP60*, encoding a U4/U6 snRNP-specific protein, showed the strongest ABA regulation and was found to be important for seed development (Raab and Hoth, 2007).

In 2001, Xiong et al. described an Arabidopsis mutant, *sad1* (*super-sensitive to ABA and drought 1*), showing enhanced sensitivity to ABA and osmotic stress during seed germination and root growth, deficient drought-induced ABA biosynthesis, and altered expression of stress-response genes. The *SAD1* sequence encodes an LSM snRNP protein similar to LSM5 proteins from various organisms ranging from yeast to human (Xiong et al., 2001a). As the sole LSM5 ortholog present in the Arabidopsis genome, *SAD1* likely regulates different aspects of mRNA metabolism, such as splicing, export and degradation. Drought and ABA treatments trigger the upregulation of ABA biosynthesis genes, with ABA enhancing particularly those encoding the last two enzymes in the ABA biosynthesis pathway (Seo et al., 2000; Xiong et al., 2001a; Xiong et al., 2001b). This suggests the existence of a feedback regulatory mechanism whereby an initial increase in ABA levels induced by drought conditions may result in the speed up of the last steps of ABA biosynthesis (Xiong et al., 2001a). *SAD1* is likely to play a critical role in regulating this feedback loop as the *sad1* mutant shows a lower degree of transcript accumulation for ABA biosynthetic genes under both drought and ABA treatments.

The floral initiator Shk1 Kinase Binding Protein1 (SKB1), also named Protein Arginine Methylationtransferase5 (PRMT5), is known to play an important role in plant development and stress responses by controlling gene expression both at the transcriptional and posttranscriptional levels (Deng et al., 2010; Sanchez et al., 2010; Zhang et al., 2011). SKB1 appears to affect gene transcription by methylating histone4 arginine3 (H4R3) and to function posttranscriptionally by methylating the Sm-like U6 snRNP protein LSM4 (Zhang et al., 2011). Mutations in the *LSM4* gene lead to altered sensitivities to both ABA and salt stress during germination and seedling development, phenotypes also exhibited by *SKB1* loss-of-function mutants (Zhang et al., 2011). RNA-seq transcriptome analyses revealed that SKB1 deficiency causes splicing defects in hundreds of genes involved in multiple biological processes, including stress responses (Deng et al., 2010; Sanchez et al., 2010; Zhang et al., 2011). The *lsm4* mutant also shows splicing defects in several genes, many of which are also affected by the *skb1* mutation, indicating that methylation of LSM4 may regulate splice site selection (Zhang et al., 2011). Interestingly, methylated levels of LSM4 are low under normal conditions but increase upon salt or ABA stress, improving splicing efficiency of certain genes or altering splicing variants of others (Zhang et al., 2011).

Another snRNP-associated protein implicated in ABA responses is STA1 (Stabilized 1). The Arabidopsis *STA1* gene encodes an mRNA splicing factor homologous to the human U5 snRNP-associated 102-kDa protein and the yeast pre-mRNA splicing factors Prp1p and Prp6p. Indeed, *stabilized1* (*sta1*) mutant plants are defective in the splicing of the stress-induced *COR15A* gene, corroborating a role for STA1 in pre-mRNA splicing (Lee et al., 2006). Furthermore, these mutants are altered in their response to ABA, salt and cold stress, showing hypersensitivity to ABA during germination and root growth and being more affected by LiCl during root growth and more chilling-sensitive during plant development than wild-type plants (Lee et al., 2006).

2.2. SR and hnRNPs Proteins

The two major classes of RBPs shown to be active in alternative splicing are members of the serine/arginine-rich (SR) and of the heterogeneous nuclear ribonucleoprotein (hnRNP) protein families. SR proteins belong to a highly conserved family of spliceosomal proteins, which have been shown in animal systems to play vital roles in both constitutive and alternative splicing by influencing the most crucial steps of spliceosome assembly (Wu and Maniatis, 1993; Kohtz et al., 1994; Manley and Tacke, 1996; Shen and Green, 2004). These essential splicing regulators share a characteristic structural domain organization and contain one or two N-terminal RRM and a C-terminal arginine/serine-rich (RS) domain. On the other hand, the hnRNP family comprises a more diverse group of RBPs, which usually contain RRM or other functionally equivalent motifs such as K-homology (KH) domains. Given their ability to associate with RNA and single-stranded (ss)DNA, they play important roles in multiple aspects of nucleic acid metabolism (reviewed in Krecic and Swanson, 1999; Martinez-Contreras et al., 2007; Han et al., 2010). Among their functions in RNA metabolism, hnRNPs have been described to utilize a variety of strategies to control splice site selection in a manner that is important for both alternative and constitutive pre-mRNA splicing. Until recently, it was generally accepted that hnRNP and SR proteins typically acted as repressors and activators of splicing, respectively, but it is now becoming evident that regulatory factors act according to the context they are in. For example, Xue et al. (2009) have shown that the polypyrimidine tract-binding protein (PTB/hnRNPI), a well-characterized hnRNP splicing regulator in mammals, is able to either activate or repress selected splice sites depending on the position of their binding site and interactions with other factors.

Earlier reports on the functional characterization of SR proteins showed them to be important for normal plant development. Analyses of transgenic Arabidopsis overexpressor lines of two SR genes, *AtSR30* and *AtRS2Z33*, revealed severe developmental abnormalities (Lopato et al., 1999; Kalyna et al., 2003). Likewise, a knockout mutant for *SR45*, a plant-specific SR-related protein, which instead of one RS domain like SR proteins includes two, one on either side of the RRM, was reported to exhibit pleiotropic defects in developmental processes (Ali et al., 2007).

The involvement of SR and SR-like splicing factors in plant stress responses is beginning to emerge. *SR45* has been shown to negatively regulate glucose and ABA signaling during early seedling development (Carvalho et al., 2010). In the presence of exogenous glucose, the *sr45-1* mutant shows a drastic delay in the greening and expansion of cotyledons under light conditions as well as severe inhibition of hypocotyl elongation in dark grown seedlings.

Accordingly, the *sr45-1* mutation confers enhanced glucose-responsive gene expression. Mutant seedlings also show enhanced sensitivity to ABA during cotyledon development and display an overaccumulation of this phytohormone in response to glucose, which correlates with a marked induction of ABA biosynthesis gene expression. Importantly, recent phenotypical characterization of the first loss-of-function mutant for a plant SR protein gene has revealed that the *Arabidopsis* SCL30a negatively regulates ABA signaling to control salt and osmotic stress responses during seed germination (Carvalho et al., unpublished results). Therefore, although responding to distinct external signals (high sugars and osmotic/salt stress), both the SR45 and SCL30a splicing factors converge on negatively regulating the ABA pathway during early plant development. This may allow seed germination and seedling growth under moderate stress, thus promoting plant tolerance to unfavorable environmental conditions.

Members of the hnRNP family have also been implicated in ABA signaling. The guard-cell-localized *Vicia faba* AAPK (ABA-Activated Protein Kinase), which regulates plasma membrane ion channels and thereby stomatal aperture, interacts with and phosphorylates AKIP1 (AAPK-interacting protein 1), an RBP homologous to the human hnRNP A/B (Li et al., 2000; Li et al., 2002). Upon ABA treatment, AKIP1 is phosphorylated by AAPK, which allows it to bind the mRNA of dehydrin *DHN1*, a stress-regulated protein thought to promote stability of enzymes and membranes under stress conditions (Li et al., 2002). A role for the AKIP protein in mRNA processing is suggested by the observation that ABA induces the relocation of this protein into nuclear speckles (Li et al., 2002), interchromatin granule clusters and storage/recycling sites for splicing factors delivering them to nearby active sites of transcription (reviewed in Misteli et al., 1997; Lamond and Spector, 2003). Similarly, the *Arabidopsis thaliana* AKIP1 homolog UBA2a (poly(U)-Binding Associated protein) also reorganizes within the nucleus in structures resembling speckles in response to ABA (Riera et al., 2006). UBA2a is an interacting partner of another hnRNP protein, UBP1 (Poly(U)-Binding Protein 1), which is involved in stimulating pre-mRNA splicing (Lambermon et al., 2000). However, UBA2a has been shown to have no effect on splicing efficiency of reporter RNAs, functioning rather in the recognition of U-rich sequences in plant 3'-UTRs and contributing to the stabilization of mRNAs in the nucleus (Lambermon et al., 2002). Contrary to AKIP1, UBA2a does not interact with and is not phosphorylated by the Open Stomata 1 (OST1) kinase, the *Arabidopsis* ortholog of AAPK, suggesting that the physiological relationship between kinases and their respective RBPs has not been conserved between *Vicia faba* and *Arabidopsis thaliana* (Riera et al., 2006).

GRP7 is a glycine-rich RNA-binding protein also showing high homology to the human hnRNP A/B (Lorkovic and Barta, 2002; Wang and Brendel, 2004) that has been recently identified as a novel splicing regulator in *Arabidopsis* (Streitner et al., 2012). This hnRNP-like protein is regulated by the circadian clock and autoregulates its expression by influencing alternative splicing of its own pre-mRNA (Staiger et al., 2003) as well as of other splicing regulators or RBPs (Streitner et al., 2012). *GRP7* was reported to be strongly repressed by ABA and osmotic stress, with a loss-of-function mutant for this gene displaying hypersensitivity to ABA during seed germination (Cao et al., 2006). However, functional analyses of other *GRP7* mutant alleles has generated conflicting data concerning these altered ABA responses (reviewed by Lorkovic, 2009). In fact, a later study by Kim et al. (2008) found no ABA-related phenotypes during germination and seedling growth for either *GRP7* knockout/knockdown plants or overexpressor lines and showed that *GRP7* affects stomatal closure during drought stress in an ABA-independent manner.

Another Arabidopsis glycine-rich type hnRNP, atRZ-1a, was first described as carrying out prominent roles in plant cold and freezing tolerance (Kim et al., 2005), functioning as an RNA chaperon during the cold adaptation process (Kim and Kang, 2006). The RZ-1a protein contains RRM s at the N-terminus and a glycine-rich region interspersed with CCHC-type zinc fingers at the C-terminus. Expression of the *RZ-1a* gene is repressed by ABA (Kim et al., 2005). Under either ABA or glucose treatment, *RZ-1a* loss-of-function mutants germinate earlier than wild-type plants, whereas *RZ-1a* overexpressing lines display retarded germination and cannot develop cotyledons (Kim et al., 2007). These genotypes exhibited similar responses under salt and dehydration stress, which could indicate that RZ-1a negatively regulates seed germination and early plant growth under these conditions in an ABA-dependent manner (Kim et al., 2007). The transcript levels of ABA biosynthesis genes remained unaltered in mutant and overexpressor plants, but changes in several germination-responsive genes were observed under salt and dehydration stress as well as upon ABA and glucose treatments, suggesting that RZ-1a affects germination under different environmental conditions by modulating the expression of these genes (Kim et al., 2007).

2.3. Other Splicing Regulators

Sugliani et al. (2010) have described yet another splicing factor implicated in ABA signaling — Suppressor of ABI3-5 (SUA). SUA is an RBP with two RRM s that interacts with the U2AF pre-spliceosomal component (Sugliani et al., 2010). This protein shares high homology with the human tumor suppressor RBM5 (RNA-binding motif protein 5), which belongs to the spliceosome complex and regulates alternative splicing of apoptosis genes (Bonnal et al., 2008). On the other hand, the *Absciscic Acid Insensitive3* (*ABI3*) gene is a major regulator of seed maturation, and mutations in *ABI3* lead to seed insensitivity to ABA during germination, desiccation intolerance and reduced longevity (Ooms et al., 1993). Sugliani et al. (2010) have shown that the pre-mRNA of the *ABI3* transcription factor possesses a cryptic intron that is alternatively spliced leading to the occurrence of two transcripts, one encoding the full-length protein and the other a truncated form. Functional analyses in the *abi3-5* and *sua-1* loss-of-function mutants indicate that SUA influences seed maturation by suppressing splicing of the cryptic *ABI3* intron. Higher abundance of SUA will favor cryptic intron retention and increase full-length ABI3 protein levels during seed maturation.

3. NON-SPLICING PROTEINS

Other RBPs not specifically or directly involved in mRNA splicing have also been associated to ABA responses in plants.

3.1. CAP Binding Proteins

The RNA cap structure, characteristic of all RNA polymerase II transcripts, consists of 7-methyl guanosine linked via a 5'–5' triphosphate bridge to the first transcribed nucleotide. Most

of the roles described for the mRNA cap are mediated by specific factors called cap-binding proteins (CBPs), which recognize and bind to this structure. In mammals, several different nuclear CBPs have been described but only two of 20 kDa (CBP20) and 80 kDa (CBP80) have been characterized in detail. In order to bind the 5' terminal cap structure of the mRNA, these two proteins need to be together in the Cap Binding Complex (CBC). This heterodimeric nuclear complex offers protection for decapping enzymes, enhances splicing and promotes the first-round of translation (Izaurrealde et al., 1994; Lewis et al., 1996a; Lewis et al., 1996b; Flaherty et al., 1997; Lewis and Izaurrealde, 1997; Cheng et al., 2006).

In plants, defects in the CBC have been described to induce ABA-hypersensitive responses. The *abh1* (ABA hypersensitive 1) mutant was isolated from activation-tagged Arabidopsis lines based on its ABA hypersensitive inhibition of seed germination (Hugouvieux et al., 2001). The mutation was mapped to the *ABH1/CBP80* gene, which is homologous to the human *CBC80* encoding the large subunit of the CBC. Besides the germination phenotype, the *abh1* mutant also shows reduced wilting during drought, ABA-hypersensitive stomatal closing and enhanced ABA-induced guard-cell calcium elevations (Hugouvieux et al., 2001; reviewed in Wasilewska et al., 2008). Similarly, RNAi-mediated silencing of the CBP80 gene in potato plants resulted in increased drought tolerance (Pieczynski et al., 2013). These transgenic plants display enhanced stomatal closure when exposed to increased ABA concentrations, probably the predominant factor underlying their improved resistance to water stress.

Hugouvieux et al. (2001) also identified an Arabidopsis homolog of the smaller subunit of the CBC (AtCBP20), showing with yeast-two hybrid assays that it can interact with ABH1/CBP80. A year later, Kmiecik et al. (2002) cloned and characterized these two Arabidopsis CBP proteins, describing CBP20 to contain a canonical RNA-binding domain (RBD) and CBP80 a MIF4G domain thought to be involved in both protein-protein and protein-RNA interactions. Analogously to the *cbp80/abh1* mutant, the *cbp20* knockout also showed alterations of responses to ABA and drought (Papp et al., 2004).

The phenotypes caused by the *abh1* lesion may result from inadequate processing of specific mRNAs encoding key regulators of certain pathways. Indeed, the *abh1* mutation causes a reduction in the steady state levels of a limited number of mRNAs, including ABA-related genes such as the *AtPP2C* gene encoding a protein phosphatase 2C involved in the regulation of ABA signal transduction (Hugouvieux et al., 2001). It also affects the correct splicing of the first intron of the MADS box transcription factor *Flowering Locus C* (*FLC* gene), which may explain the early-flowering phenotype that has also been described as a consequence of disruption of the *ABH1* gene (Kuhn et al., 2007).

Importantly, the Arabidopsis CBC has also been implicated in alternative splicing (Raczynska et al., 2010). Splicing profiles were compared between wild type plants and the *cbp20* and *cbp80/abh1* single and double mutants by use of an RT-PCR alternative splicing panel (Simpson et al., 2008). Using this tool, Raczynska et al. (2010) were able to analyze 435 alternative splicing events in Arabidopsis, concluding that both ABH1/CBP80 and CBP20 affect alternative splicing of various stress-related genes, preferentially at the 5' splice site of the first intron. This is in agreement with the current model for animal systems that the CBC promotes 5' splice site selection within the first intron of pre-mRNAs.

3.2. RNA Helicases and Pentatricopeptide Repeat Proteins

RNA helicases function as molecular motors that rearrange RNA secondary structure or dissolve RNA-protein complexes. They are hence involved in many steps of RNA metabolism, ranging from transcription to RNA degradation, including pre-mRNA splicing, ribosome biogenesis, translation initiation and organellar gene expression (reviewed in Linder, 2006). In yeast, the DEAD (Asp-Glu-Ala-Asp) box-type helicases Sub2, Prp28 and Prp5 are required for *in vivo* splicing (reviewed in Staley and Guthrie, 1998) and in higher eukaryotes, the RNA helicases p68 and p72 are involved in alternative mRNA splicing (Honig et al., 2002; Liu, 2002; Guil et al., 2003).

In plants, RNA helicase gene families are larger and more diversified than in other systems, with 115 and 113 members in rice and Arabidopsis, respectively (Linder and Owtrim, 2009; Umate et al., 2010). Very little is known about the function of these families in plants, but the functional characterization of a few of their members has implicated them in abiotic stress responses, namely through the ABA pathway. Just recently, a plant DEAD box RNA helicase, RCF1 (Regulator of CBF gene expression 1), has been implicated in RNA splicing — *rcf1-1* mutant plants display mis-spliced cold-responsive genes under cold stress (Guan et al., 2013).

The Arabidopsis gene *LOS4* (*low expression of osmotically responsive genes 4*) encodes a DEAD box RNA helicase, with a mutant allele for this gene, *cryophyte*, being isolated in a genetic screen due to its enhanced cold tolerance (Gong et al., 2005). Besides being more resistant to chilling than wild-type plants, *cryophyte* mutants also display a hypersensitive response to ABA during germination and early seedling development. The observation that the *cryophyte* mutant accumulated stronger polyadenylation signals (hallmarks of translationally-competent mRNAs) in nuclei than did wild-type cells led to the suggestion that the *cryophyte* mutation influences mRNA export of some gene(s) involved in ABA signal transduction (Gong et al., 2005).

Two other Arabidopsis RNA helicases, Stress Response Suppressor 1 (STRS1) and STRS2, have been proposed as negative regulators of multiple abiotic stress responses, acting through both ABA-dependent and ABA-independent pathways (Kant et al., 2007). Mutations in either gene render increased tolerance to salt, osmotic and heat stresses and, consistent with their stress-tolerant phenotypes, *strs* mutants exhibit enhanced expression of both ABA-dependent and ABA-independent stress-responsive genes (Kant et al., 2007). Intriguingly, despite inducing upregulation of ABA-dependent stress-response genes, the absence of the STRS1 and STRS2 proteins did not result in ABA hypersensitivity — in fact, the *strs* mutants appear to be insensitive to the ABA inhibition of seed germination. Although their mode of action is yet unclear, STRS1 and STRS2 present themselves as regulatory nodes linking salt, osmotic, heat and ABA signaling networks.

Most mitochondrial proteins are encoded by nuclear genes, but a small fraction is encoded by the mitochondrial genome. The processing of mitochondrial RNAs, including intron splicing and RNA editing, requires the action of nuclear-encoded proteins such as RNA helicases and Pentatricopeptide Repeat (PPR) proteins (reviewed in O'Toole et al., 2008; Schmitz-Linneweber and Small, 2008; Kohler et al., 2010; Liu et al., 2010; He et al., 2012). The *ABA overly-sensitive 5* (*abo5*) and *abo6* mutants were isolated in a genetic screen for ABA-mediated inhibition of primary root growth, with the mutations being mapped to a PPR protein and a DEXH (Asp-Glu-X-His) Box RNA helicase, respectively (Liu et al., 2010; He et al., 2012). Both these proteins are involved in the correct splicing of mitochondrial RNAs in Arabidopsis.

PPR proteins form a large family of nuclear-encoded RBPs, particularly prevalent in terrestrial plants, which are mostly targeted to chloroplasts and mitochondria. Liu et al. (2010) have shown that a mutation in the *ABO5* PPR gene impairs splicing of the *nad2* NADH dehydrogenase subunit 2 of the mitochondrial complex I in the electron transport chain and leads to ABA hypersensitive phenotypes during early seedling development, such as delayed cotyledon greening and root growth. These might partially result from hyperaccumulation of Reactive Oxygen Species (ROS) in the *abo5* mutant (Liu et al., 2010), as disruption of ROS-producing genes impairs ABA inhibition of seed germination and root growth (Kwak et al., 2003). In addition, like many other ABA-related mutants, *abo5* shows enhanced sensitivity to high sugar concentrations (Liu et al., 2010). At the molecular level, not only did the *abo5* mutation impair splicing in the *nad2* gene, but also resulted in increased complex I and IV mitochondrial gene expression upon ABA treatment, despite the fact that *abo5* mutants are impaired in ABA-regulated gene expression (Liu et al., 2010).

The DEXH box RNA helicase encoded by the *ABO6* gene is also crucial for proper ABA signal transduction (He et al., 2012). When *abo6* mutants are exposed to increased levels of ABA, they exhibit various ABA-hypersensitive phenotypes, namely reduced seed germination and early seedling growth as well as reduced primary root growth and stomatal opening when compared to wild type plants (He et al., 2012). Similarly to what happens in *abo5*, ABA also enhances the production of ROS in *abo6* mutants. Moreover, He et al. (2012) observed that the *abo6* mutants display reduced content of both auxins and auxin carriers, probably due to ABA-mediated ROS overproduction. Accordingly, exogenous application of auxin rescued the altered *abo6* ABA responses to both root growth and germination. Finally, the *abo6* mutation was found to impair splicing of the mitochondrial complex I *NAD1b*, *NAD1c*, *NAD2a*, *NAD4* and *NAD5a* genes and to induce the accumulation of other mitochondrial transcripts (He et al., 2012).

3.3. Other RNA-Binding Proteins

In a screen for ABA-hypersensitive *Arabidopsis* transposon insertion lines, Lu and Fedoroff (2000) isolated the *hyponastic leaves 1* (*hyl1*) mutant displaying increased sensitivity to the inhibition of seed germination and root growth by ABA. The *HYL1* gene encodes a nuclear-localized RNA-binding protein that specifically binds double-stranded (ds)RNA (Lu and Fedoroff, 2000). The *hyl1* mutation causes an increase in basal abundance of ABA-inducible genes, namely of those encoding the ABI5 transcription factor as well as two mitogen-activated protein kinase (MAPK) proteins, which have been shown to phosphorylate ABI5 (Lu et al., 2002). This suggests that the ABA hypersensitivity of the *hyl1* mutant is due to elevated expression of stress MAPK signaling components and that the HYL1 protein could be involved in either transcription regulation or mRNA stability (reviewed in Lu and Fedoroff, 2000; Lu et al., 2002; Kuhn and Schroeder, 2003).

Disruption of another RNA processing component, the poly(A)-specific ribonuclease (PARN), a deadenylase involved in the first step of mRNA degradation, also causes abnormal ABA responses in *Arabidopsis*. Nishimura et al. (2005) characterized in detail a leaky transposon insertion mutant for this gene, *ahg2-1* (*ABA-hypersensitive germination 2*), and found that it is oversensitive to ABA both during germination and at adult rosette stages. The *ahg2-1* mutation causes more ABA to accumulate in seeds and later in development, as well as

in response to the osmotic stressor mannitol, which could explain the observed ABA phenotype. In addition, *ahg2-1* mutant plants are also hypersensitive to salicylic acid (SA) and resistant to drought stress (Nishimura et al., 2005). At the molecular level, microarray analysis showed several stress-induced genes to be upregulated in the mutant. Clustering analysis suggested that this pattern is very similar to that of upregulated genes in ABA- or SA-treated wild-type plants (Nishimura et al., 2005). The authors speculate that PARN/AHG2 has a pivotal role in downregulating target genes by destabilizing mRNAs to maintain proper stress responses. Interestingly, the *PARN/AHG2* gene undergoes alternative splicing, but the physiological roles of the variant transcripts have not yet been investigated.

A further study providing evidence for a connection between RNA metabolism and ABA signaling describes the involvement of the RNA-binding protein Tudor staphylococcal nuclease (TSN) in plant stress responses (dit Frey et al., 2010). TSN is a multifunctional protein that in humans has been implicated in a variety of cellular processes, including gene transcription and pre-mRNA splicing (Yang et al., 2007; Gao et al., 2012). Both the sequence and the domain architecture of TSN proteins are well conserved in eukaryotes. The Arabidopsis genome contains two highly similar genes, designated *TSN1* and *TSN2*, encoding Tudor proteins with four staphylococcal nuclease (SN) domains, followed by a Tudor domain connected to a fifth SN domain. The Tudor domain was originally identified as a region of 50 amino acids found in the *Drosophila* Tudor protein, and has been subsequently found within a number of proteins involved in RNA binding (reviewed in Pek et al., 2012). Phenotypical analysis of a null *tsn1 tsn2* double mutant, obtained by crossing the single T-DNA insertion *tsn1* and *tsn2* mutants, determined TSN to function in the control of RNA stability during plant stress responses (dit Frey et al., 2010; reviewed in Ambrosone et al., 2012; Nakaminami et al., 2012). In fact, germination, seedling growth and survival under high salinity stress were drastically affected in *tsn1 tsn2* plants, with these double mutants also displaying hypersensitivity to ABA during germination (dit Frey et al., 2010).

A putative dsRNA binding protein, FIERY2/CTD-phosphatase-like 1 (FRY2/CPL1), has also been implicated in ABA and stress responses (Xiong et al., 2002). FRY2/CPL1 possesses two dsRNA-binding domains and a conserved region with similarity to the catalytic domain of RNA polymerase II Carboxy-terminal Domain (CTD) phosphatases found in yeast and animals. CTD phosphorylation is known to influence cotranscriptional pre-mRNA processing, namely splicing and poly(A) site cleavage (Bird et al., 2004). The presence of this catalytic domain in FRY2 suggests that it may possess catalytic functions, and indeed Koiwa et al. (2002) have shown that the FRY2 recombinant protein exhibits phosphatase activity. As FRY2 contains dsRNA-binding domains, its enzymatic activity could be regulated by dsRNA (Xiong et al., 2002). *fry2* mutations result in the induction of the Drought Responsive/C-Repeat (DRE/CRT) class of stress-responsive genes upon cold, salt and ABA treatments. Furthermore, *fry2* mutants display insensitivity to salt and ABA during seed germination and early seedling development, but are hypersensitive to ABA during root elongation, and mutant seedlings also show increased susceptibility to freezing damage (Xiong et al., 2002). FRY2 is a negative transcriptional regulator of stress-related genes playing different roles and exhibiting ABA responsiveness during various developmental stages.

Recently, Jung et al. (2013) selected an ABA-regulated RBP, which they named ARP1 (ABA-regulated RNA-binding Protein), from the GENEVESTIGATOR expression database for detailed functional characterization. The *ARP* gene, downregulated by ABA, encodes a nuclear protein containing a well-conserved RRM and is present in Arabidopsis as a unique

gene. To assess the potential role of this RBP in ABA responses, Jung et al. (2013) analyzed ARP1-overexpressing transgenic *Arabidopsis* plants and a loss-of-function T-DNA insertion mutant, *arp1*. Upon exogenous ABA application, similar phenotypes were observed for both the null-mutant and the overexpression lines — hypersensitivity to ABA during seed germination and cotyledon greening (Jung et al., 2013). In accordance with the ABA germination phenotype, several germination-responsive genes were upregulated in *arp1* and ARP1-overexpression plants (Jung et al., 2013). The fact that ARP1 overexpression induced the same effects as knocking out the corresponding gene suggests that overaccumulation of ARP1 inhibits its normal function and thus that levels of its transcript need to be tightly regulated (Jung et al., 2013). The findings of this recent study once again provide evidence for involvement of an RBP in ABA and abiotic stress responses in plants.

CONCLUSION

Studies on the RNA regulation of plant responses to abiotic stress have shown considerable progress in the past decade. As reviewed here, the functional and molecular characterization of several plant RBPs has provided evident links between mRNA processing mechanisms and ABA-mediated plant stress responses. In particular, the loss- or gain-of-function of genes encoding various splicing-related factors, such as snRNPs or SR and hnRNP proteins, have been shown to result in striking ABA-response phenotypes at various stages of plant development. Interestingly, the same has been observed when knocking out other RBP genes, such as those coding for CBPs, RNA helicases, PPR proteins, poly(A) processing enzymes or dsRBPs. The fact that members of a wide range of classes of RNA-metabolism proteins appear to be indispensable for adequate ABA biosynthesis or signal transduction supports a global role for posttranscriptional control of gene expression in regulating plant responses to environmental cues.

To explain the well-defined plant phenotypes associated with altered RBP levels and dissect the role of these factors in the response to stress, the cellular and molecular mechanisms underlying their mode of action in regulating the ABA pathway will need to be uncovered. A key step towards this goal will be the identification of the direct RNA targets and ligands of these RBPs. Importantly, Streitner et al. (2012) recently succeeded in validating putative RNA targets for the hnRNP GRP7 protein by means of RNA immunoprecipitation (RIP) of ribonucleoprotein complexes. Using this RIP approach, the authors were able to confirm direct binding of GRP7 to seven target transcripts that had been identified as showing reciprocal splicing patterns in GRP7 mutant and overexpressing lines using a high-resolution RT-PCR-based alternative splicing panel. Future similar approaches hold much promise in unravelling the mechanistic basis of posttranscriptional regulation of plant ABA-mediated stress responses.

Table 1. Plant RNA-binding Proteins Involved in ABA Stress Responses

	Gene name	Locus ID	Domains (#)	Associated phenotypes	References
Splicing factors					
<i>snRNP factors</i>					
Sm-like snRNP protein (homolog of human LSM5 and yeast Lsm5)	<i>SAD1/LSM5</i>	At5g48870	Sm (1)	<i>sad1</i> mutant hypersensitive to ABA and drought stress during germination and root growth as well as deficient in drought-induced ABA biosynthesis	Xiong et al., 2001a
Sm-like U6 snRNP protein (homolog of human Lsm4 and yeast Lsm4)	<i>LSM4</i>	At5g27720	Sm (1)	<i>lsm4</i> mutant hypersensitive to ABA and salt stress during germination and seedling development	Zhang et al., 2011
U5-snRNP specific protein (homolog of human U5 snRNP-associated protein Prp6b-like and yeast Prp splicing factors)	<i>STA1/U5-102kDa</i>	At4g03430	TPR (3) HAT (15) TPR-like (2) Prp1_N (1)	<i>sta1</i> mutant hypersensitive to ABA and LiCl salt stress during germination and root growth as well as over sensitive to chilling	Lee et al., 2006
<i>SR and hnRNPs proteins</i>					
SR-like protein	<i>SR45</i>	At1g16610	RRM (1), RS (2)	<i>sr45-1</i> mutant hypersensitive to ABA and glucose during early seedling development	Carvalho et al., 2010
SR protein	<i>SCL30a</i>	At3g13570	RRM (1) RS (1)	<i>sc30a-1</i> insertion mutant hypersensitive to ABA as well as to salt and osmotic stress during seed germination	Carvalho et al., unpublished
hnRNP (homolog of human hnRNP A/B)	<i>AKIP1</i>	AKIP1 (<i>Vicia faba</i>)	RRM (1)	ABA activates the RNA-binding activity of AKIP1 and induces its relocation into nuclear speckles	Li et al., 2002
hnRNP (GRP) (homolog of <i>V. faba</i> AKIP1 and human hnRNP A/B)	<i>UBA2a</i>	At3g56860	RRM (2)	ABA induces relocation of UBA2a into nuclear speckles	Riera et al., 2006
hnRNP (GRP) (homolog of human hnRNP A/B)	<i>GRP7</i>	At2g21660	RRM (1)	<i>grp7-1</i> mutant hypersensitive to ABA during germination; conflicting data with other mutant alleles	Cao et al., 2006; Kim et al., 2008
hnRNP (GRP) (homolog of human hnRNP G)	<i>RZ1-a/hnRNP-G2</i>	At3g26420	RRM (1) ZnD (1)	<i>RZ1a</i> knockout mutants/overexpressor lines insensitive/hypersensitive to ABA and glucose as well as to salt and dehydration stress during germination and seedling growth	Kim et al., 2007
<i>Other splicing regulators</i>					
RBP, splicing factor (homolog of human RBM5)	<i>SUA</i>	At3g54230	RRM (2) ZnD (1)	ABA seed maturation-related phenotype	Sugliani et al., 2010

Non-splicing proteins					
Cap-binding proteins					
nuclear cap-binding protein (homolog of human CBP80 and yeast Cbc1)	<i>ABH1/CBP80</i>	At2g13540	MIF4G (1) ARM (3)	<i>abh1</i> mutant hypersensitive to ABA during germination and stomatal closure as well as tolerant to drought stress	Hugouvieux et al., 2001
nuclear cap-binding protein (homolog of human CBP20 and yeast Cbc2p)	<i>CBP20</i>	At5g44200	RRM (1)	<i>cbp20</i> mutant hypersensitive to ABA during germination and stomatal closure as well as tolerant to drought stress	Papp et al., 2004
RNA helicases and Pentatricopeptide Repeat proteins					
DEAD Box RNA helicase	<i>cryophyte/LOS4</i>	At3g53110	DEAD Box (8)	<i>cryophyte/los4-2</i> mutant hypersensitive to ABA during germination and early seedling development as well as tolerant to low temperatures	Gong et al., 2005
DEAD Box RNA helicases	<i>STRS1</i> <i>STRS2</i>	At5g08620 At5g08620	DEAD Box (9)	<i>strs1</i> , <i>strs1a</i> , <i>strs2</i> , <i>strs2a</i> mutants insensitive to ABA, salt and osmotic stress during germination	Kant et al., 2007
PPR protein	<i>ABO5</i>	At1g51965	PPR (6)	<i>abo5</i> mutant hypersensitive to ABA during early seedling development and root growth and to sugars during early growth	Liu et al., 2010
DEXH Box RNA helicase	<i>ABO6</i>	At5g04895	dsRBD (1) DEXH Box (1)	<i>abo6</i> mutant hypersensitive to ABA during germination, early seedling development, root growth and stomatal closure as well as tolerant to drought stress	He et al., 2012
Other RNA-binding proteins					
dsRBP	<i>HYL1</i>	At1g09700	dsRBD (2)	<i>hyl1</i> mutant hypersensitive to ABA during germination and root growth as well as less sensitive to auxins and cytokinins	Lu and Fedoroff, 2000
Poly(A) Ribonuclease	<i>PARN/AHG2</i>	At1g55870	Ribonuclease HD	<i>ahg2-1</i> mutant hypersensitive to ABA and salicylic acid during germination and plant development as well as tolerant to drought stress	Nishimura et al., 2005
Tudor RBP	<i>TSN1</i> <i>TSN2</i>	At5g073550 At5g61780	SN (5) Tudor (1)	<i>tsn1 tsn2</i> double mutants hypersensitive to ABA and salt during germination and seedling growth	dit Frey et al., 2010
putative RBP	<i>FRY2/CPL</i>	At4g21670	dsRBD (2) CTD (1)	<i>fry2</i> mutant insensitive to ABA and salt during germination and early seedling development but hypersensitive to ABA during root growth; also more susceptible to freezing damage	Xiong et al., 2002
putative RBP	<i>ARP1</i>	At3g54770	RRM (1)	<i>ARP1</i> knockout mutants/overexpressor lines hypersensitive to ABA as well as to salt and dehydration stress during germination and seedling growth	Jung et al., 2013

Abbreviations for protein domains are as follows: TPR, Tetratricopeptide; HAT, Half A Tetratricopeptide repeat; PRP1_N, PRP1 splicing factor, N terminal; RRM, RNA-Recognition Motif; RS, arginine/serine dipeptides; ZnD, Zinc-finger domain; MIF4G, Initiation Factor eIF-4 gamma; ARM, ARM Repeat Fold; DEAD box, Asp-Glu-Ala-Asp box; PPR, Pentatricopeptide Repeats; dsRBD, double stranded RNA-binding Domain; DEXH box, Asp-Glu-X-His box; RibonucleaseHD, Ribonuclease H-like domain SN, staphylococcal nuclease; RBP, RNA-binding Protein; CTD, Carboxy-Terminal Domain; RBM5, RNA Binding Motif Protein 5.

Chapter 21

COMPREHENSIVE ANALYSES OF ALTERNATIVE EXONS IN NEURONALLY DIFFERENTIATED P19 CELLS

Hitoshi Suzuki and Toshifumi Tsukahara*

School of Materials Science, Japan Advanced Institute of Science and Technology
Nomi, Ishikawa, Japan

ABSTRACT

Alternative splicing occurs in most human genes and contributes to protein diversity by producing multiple mRNAs from each gene. Many of these alternative isoforms are expressed in a spatio-temporal manner and play important functional roles in many biological processes including neuronal events. Here, neuronal-specific splicing was comprehensively investigated by using P19 cells. GeneChip Exon Array analyses were performed of total RNA purified from cells during different stages of the differentiation process. Nine filtering conditions were used to efficiently and readily extract alternative exon candidates. A total of 262 candidate exons (236 genes) were obtained. Semi-quantitative RT-PCR results of 30 randomly selected candidates suggested that the expression levels of 87% of the candidates were at least 2-fold different between undifferentiated and differentiated cells. Gene ontology and pathway analyses also showed that many of these 236 candidate genes played important roles in neuronal events. These results suggested that this novel method to determine alternative exons was successful and efficient. In addition to the known neuronal functions, informatics analyses demonstrated that alternative splicing events of 11 candidate genes played important cell cycle functions. These results suggest that this novel method also provides a way to determine the functional roles of previously unknown alternative splicing events.

INTRODUCTION

The human genome project estimates that only approximately 23,000 human genes encode proteins (1). Therefore, the number of human genes is only slightly higher than the number of genes found in lower eukaryotes such as worms. However, more than 90% of human genes are subjected to alternative splicing (2). This percentage of alternative exons in humans is remarkably higher than the percentage in lower eukaryotes (3). Therefore, alternative splicing is very important for higher eukaryotes. Alternative splicing changes the usage of exons and generates multiple different transcripts from a single gene. Each of these transcripts is translated into a different protein isoform. Thus, alternative splicing enhances proteomic diversity and supports increased complexity in higher eukaryotes (4). Many alternative isoforms play different or even opposed functions to other isoforms generated from the same gene. Furthermore, some of these alternative isoforms play very important roles in several biological processes (5, 6). Many alternative splicing events occur in specific spatio-temporal manners and some of these splicing events are controlled by alternative splicing regulators. Several splicing regulators (such as nPTB, Nova1, and Fox-1) and their target pre-mRNAs are characterized in neuronal tissue (7-9). Thus, in depth understandings of the alternative splicing networks are very important since these splicing networks are responsible for a large portion of the proteins that are generated from the gene expression network (10).

There are five basic types of alternative splicing: exon skipping, 5' splice site (ss) selection, 3' ss selection, mutually exclusive exons, and intron retention (4). These are the basic types of splicing and involve differential uses of splice sites. In addition to these basic types of splicing, multiple polyadenylation (poly-A) sites and multiple promoters can also result in different mRNA transcripts being generated from the same gene. 3' ss selection and/or multiple poly-A signals can result in alternative termination points for transcripts. By contrast, multiple promoters can cause transcription to initiate from different points, which results in the generation of transcripts with different 5' exons (5, 11). These different types of alternative splicing can sometimes occur together and result in complicated splicing. The differential usage of exons through alternative splicing, multiple poly-A sites, and multiple promoters results in changes to partial regions of the amino acid codes.

In the past several years, several new technologies (such as microarrays and high-throughput sequencing) were developed that permit genome-wide analyses of alternative splicing [reviewed in (12)]. There are two main types of microarrays used to detect alternative splicing events: junction arrays and exon arrays. Probes for exon arrays are designed to detect each individual exon of known or predicted genes. By contrast, probes for junction arrays are designed to detect exon-exon junctions. GeneChip Exon Arrays (supplied by Affymetrix) are accessible and convenient since the protocols used for sample preparation are very similar to those used for sample preparation for standard gene expression profiling with GeneChip Gene Arrays. In fact, a study found that Gene Arrays are comparable to Exon Arrays for gene expression profiling (13). Thus, Exon Arrays are one of the more convenient tools to investigate genome-wide alternative splicing events. In the last few years, several studies were published that analyzed alternative splicing in exon arrays. However, only a few studies found potential alternative exons in exon arrays and then validated the results by RT-PCR (14-18). Moreover, only a couple of reports validated potential alternative exons and then subjected these exons to gene ontology (GO) analyses or pathway analyses (18).

P19 cells (P19 mouse embryonic carcinoma cells) are multi-potent cells that can be differentiated into neuronal cells or cardiomyocytes depending on the concentration of retinoic acid in the medium (19, 20). We previously reported how neuronal-specific splicing of myocyte enhancer factor-2c (Mef2c) exon β is regulated in P19 cells (21). Mef2 proteins are a family of transcription factors that play important roles in muscle differentiation and synaptogenesis (22, 23). We found that Forkhead box-1 (Fox-1) promotes inclusion of Mef2c exon β via the GCAUG sequence that is located in the intron downstream of Mef2c exon β (21). These results suggested that the machinery necessary for alternative splicing is present in P19 cells and that P19 cells provide a useful model system to study alternative splicing events. There are likely to be many alternative splicing events that are regulated by transcription factors in a neuronal-specific manner, in addition to Mef2c exon β and Fox-1, when P19 cells are differentiated into neuronal cells. Furthermore, other regulators of these splicing events may be expressed in a neuronal-specific manner.

In this study, we attempted to comprehensively investigate neuronal splicing events in P19 cells. We performed GeneChip Exon Arrays using total RNA purified from undifferentiated P19 cells (Day 0), neuronal differentiated cells (Day 7), and early glial stage cells (Day 10). We generated nine filtering conditions for the probe sets based on their annotations, estimated gene expression signals, splicing indices (SIs), detection above background (DABG) values, and alternative splicing predictions. All of these conditions were based on simple parameters that avoided complicated statistics and used freely provided annotations. We extracted 262 candidate differentially alternatively spliced (DAS) exons. Furthermore, we used RT-PCR to confirm that there were greater than 2-fold differences in the expression levels of these candidates between undifferentiated and neuronal differentiated cells. The results of the RT-PCR experiments suggested that approximately 87% of the 262 candidate DAS exons were subjected to alternative splicing in a neuronal-specific manner. These results suggest that this novel method is useful to extract candidate exons. Finally, we used informatics approaches such as GO analyses, text mining, and pathway analyses to confirm that the candidate exons were important for neuronal events.

MATERIALS AND METHODS

Cell Culture and RNA Purification

P19 cells were maintained in Minimum Essential Medium, α (α -MEM; Sigma) supplemented with 10% fetal bovine serum (FBS; Sigma). To induce neuronal cell differentiation, P19 cells (1×10^5 cells/mL) were treated with 1 μ M of all trans-retinoic acid (RA) for 4 days in the 10 cm petri dish (Falcon) with α -MEM containing 10% FBS as described previously (21, 24). Total RNAs were collected from undifferentiated cells (Day 0), from cells during neuronal differentiation (Day 1, 4, 7), and from cells in the early glial stage (Day 10) using RNeasy (Qiagen).

Exon Arrays

cDNA and cRNA syntheses were performed according to the manufacturer's instructions using total RNA from undifferentiated cells, neuronal differentiated cells, and early glial stage cells. These samples were then hybridized to GeneChip Mouse Exon 1.0 ST Arrays (Exon Array, Affymetrix). Hybridization, washing, and scanning were performed with the GeneChip Fluidics Station and the GeneChip Scanner (Affymetrix) according to the manufacturer's instructions. The accession number for the Exon Array data is GSE23710.

Signal Estimations

Signal data were acquired in CEL files and were sketched, normalized, and summarized with the Probe Logarithmic Intensity Error method for exon level intensities and the IterPLIER method for gene level intensities using the Affymetrix Expression Console. In both cases, the core option, which limits the analyses to probe sets that are mapped to RefSeq and the mRNA of full length coding sequences, was used. The presence or absence of each probe set was determined by the DABG p-values. The signal estimates of the three time points with biological duplicates (Days 0, 7, and 10) were summarized with various annotations supplied by Affymetrix such as probe set positions, transcript accessions, and probe sequences.

Extraction of Candidate Exons and Genes

In an exon array, there are multiple probe sets for each exon and the probe set intensities represent the expression levels of exons. Normalized intensity (NI) values, which are the ratios of the probe set intensities to the gene intensities, were estimated for the three time points (NI_{d0}, NI_{d7}, and NI_{d10}). Splicing index (SI) values were calculated by taking the log ratios (base 2) of the averaged NIs of the biological duplicates. Probe sets that had high potential to cross-hybridize based on the annotations were removed from the analyses. The splicing patterns of the exons were predicted with UCSC BLAT (Blast Like Alignment Tool) searches (<http://genome.ucsc.edu/cgi-bin/hgBlat>). An automatic system to predict alternative splicing was established with several probe-filtering procedures (<http://www.w-fusion.com/E/>) using the results of the UCSC BLAT searches and BLAST (Basic Local Alignment Tool) searches. A detailed explanation of the extraction method for the candidate exons can be found in the Results section.

A gene was defined as expressed when more than 50% of the probe sets for that gene had DABG p-values less than 0.05 in both biological duplicates of a time point. Only genes that were defined as expressed at either Day 0 or Day 7 were used for the analyses. Two categories of expressed genes were created for the gene expression analyses. These categories were differentially expressed (DEX)-up and DEX-down. Gene expression levels in the DEX-up group at Day 7 were 2–10-fold greater than the expression levels at Day 0, and were also greater than the expression levels at Day 10. By contrast, the gene expression levels in the DEX-down group at Day 7 were 2–10-fold less than the expression levels at Day 0, and were also less than the expression levels at Day 10.

Table 1. Percentages of the relative amounts of alternative exons were compared between Day 0 and Day 7

Gene	Probeset ID	SI _{d7}	Exon type	Neural AS	Change of PCR product (%/%)	Length (nt)	Novel splicing

The differences in the relative amounts of alternative exons are indicated by: (-): less than 2-fold or the change in Day 10 is larger than Day 7 against Day 0; (+): more than 2-fold but less than 10-fold; (++): more than 10-fold. D0: percentage of Day 0; D7: percentage of Day 7; Br: percentage of brain tissue; He: percentage of heart tissue; Ki: percentage of kidney tissue; Li: percentage of liver tissue; Sp: percentage of spleen tissue; and Sk: percentage of skeletal muscle.

Semi-Quantitative RT-PCR

Total RNA was prepared from P19 cells as described above. Total RNA from mouse tissues was commercially available (Ambion, Funakoshi). cDNA was made from 2 µg of total RNA using SuperScript III (Invitrogen) and 0.5 µg of oligo dT primer in a 20 µL reaction. The cDNA was then used as the template for the PCR assays. The PCR assays were performed with GoTaq polymerase (Promega) and specific primers. The sequences of the DNA primers, the number of cycles, and the annealing temperatures that were used for the candidates are described in Supplemental Table 1. The primer sequences, the number of cycles, and the annealing temperatures for β -Actin and GluR1 were previously described (21). PCR products were analyzed with 6% polyacrylamide gels. The gels were stained with SYBR Green I (Takara), and the images were analyzed with a LAS-3000 imaging system (Fuji Film). The PCR product sequences were confirmed with a 3100 DNA sequencer (ABI). The accession numbers of the sequences for the novel alternative variants are listed in Table 3. Densitometry measurements were made with MultiGauge v 3.0 software (Fuji Film) and each experiment was performed more than three times to confirm reproducibility.

GO Analyses, Pathway Analyses, and Text Mining

GO analyses of the genes with candidate exons, the genes in the DEX-up group, and the genes in the DEX-down group were performed. Furthermore, statistically significant biological process terms were obtained with Fisher's exact tests (p -values ≤ 0.01) using Pathway Studio (Ariadne Genomics) for pathway analyses and text mining.

RESULTS

Extraction of Alternative Exon Candidates

While most exons are constitutive exons, alternative splicing occurs in more than 90% of human genes (2). Most of the probes that we analyzed were constitutive exons because we used core exon probes. Therefore, we generated nine filtering conditions to extract exons that were candidates for alternative splicing. (Condition 1) We removed the first and last probe sets of each gene because the outermost probe sets are usually designed to assess potential exons that are outside of the genes. (Condition 2) We excluded probe sets with sequences longer than 500 nucleotides (nt) because the length of most human exons is shorter than 300 nt and probe sets with longer sequences indicate that the untranslated region is included. (Condition 3) Probe sets that had high potential to cross-hybridize based on the annotations were removed from the analyses. With these three filtering conditions, 221,336 core exon probe sets for 16,661 genes were reduced to 159,552 probe sets for 15,238 genes.

(Condition 4) To identify alternative exon splicing events, we only included genes that were expressed at both Day 0 and Day 7, and exons that had detectable expression levels at one of these two time points. The reliability of gene expression levels was determined with DABG p -values of probe sets as described in the Materials and Methods. (Condition 5) For exon level

filtering, we only included probe sets that displayed significant DABG p-values ($p < 0.05$) at either Day 0 or Day 7. These filtering conditions reduced the number of candidate probe sets to 94,780. The Id7 and A-values of these probe sets were plotted, and most were clustered in the middle of the graph where $SI_{d7} = 0.00$. Therefore, these probe sets had small absolute SI_{d7} values (ABS_SI_{d7}) and were not related to alternatively spliced exons at Day 0 and Day 7. (Condition 6) We established a threshold for ABS_SI_{d7} (± 1.35 of SI_{d7} ; 2.55-fold). The SI value of a probe set represents the difference in the exon expression levels between two time points adjusted to the gene expression levels.

Figure 1. Statistical analyses of candidate exons. (A) Percentages of the predicted alternative exons. A total of 2,650 probe set ID sequences with ABS_SI_{d7} values that were greater than 1.0 for the eighth condition were searched. The seventh condition was excluded. It was then predicted whether or not the probe sets that were found represented alternative exons. Hole dots show percentages of alternative exons in each of the 50 probe sets from the largest ABS_SI_{d7} to approximately 1.0. The broken line shows the approximation curve. The vertical broken line shows the threshold that was used ($ABS_SI_{d7} = 1.35$). The horizontal broken line (27.9%) shows the percentage of predicted alternative exons based on the eighth condition of Table 1. (B) Percentages of the different types of alternative splicing in the DAS exons. Potential alternative splicing events were analyzed for 262 probe set ID sequences through UCSC BLAT searches.

However, the SI values of probe sets do not consider relationships between adjacent exons. Therefore, we also extracted adjacent downstream or upstream probe sets that were expressed (no cross-hybridization; DABG p-values ≤ 0.05). (Condition 7) If at least one of the adjacent probe sets had an ABS_SI_{d7} less than 0.667, then the probe sets were retained. Theoretically a probe set indicates the border between alternative and constitutive exons. Thus, because most probe sets are designed to assess constitutive exons, it is possible that there were many constitutive exons in the remaining 1,107 exons. (Condition 8) We searched the sequences of the remaining probe sets in the UCSC BLAT genome and predicted whether the probe set sequences indicated alternative exons. To this end, a probe set was categorized as an alternative

exon if the sequence aligned with the alternative exon region in the UCSC gene. In addition, if a probe set sequence aligned with multiple fragments of the mRNA sequence in the Genbank and EST databases and also skipped multiple other fragments, then the probe set was categorized as an alternative exon candidate. We also generated an automated system to evaluate the sequences and confirm the results (data not shown). Approximately 28% of the remaining probe sets (309 probe sets) were predicted to be alternative exons (Figure 1A). (Condition 9) Finally, we compared Sid7 and Sid10. We retained all of the probe sets that had a greater SI on Day 7 than on Day 10 when Sid7 was positive. We also kept the probe sets that had a lower SI on Day 7 than on Day 10 when Sid7 was negative. With all of these filtering conditions, we extracted a total of 262 probe sets. Within these 262 probe sets, all of the different types of alternative splicing events could be found (Figure 1B). These 262 probe sets were defined as DAS exons that were potentially alternatively spliced in a neuronal-specific manner.

Semi-Quantitative RT-PCR of the Candidate Exons

Figure 2. Semi-quantitative RT-PCR results. The results of semi-quantitative RT-PCR experiments and subsequent densitometric analyses were plotted. The amounts of each PCR product were divided by the total amounts in each lane. The bars and error bars in the histogram indicate the percentages and the standard errors. The numbers on the right side of graph indicate the lengths of the PCR products. The numbers at the bottom of the graph show the time points. Day 0 indicates the undifferentiated stage, Day 7 indicates the neuronal stage, and Day 10 indicates the early glial stage.

To examine whether the potential DAS exons actually were subjected to alternative splicing during neuronal differentiation of P19 cells, we performed semi-quantitative RT-PCR experiments. We randomly selected 30 of the 262 exons for these experiments. Typical patterns of the RT-PCR results are shown in Figure 2. Densitometric analyses showed that the alternative splicing of 13 of these 30 exons was greater than 10-fold different between undifferentiated and neuronally differentiated P19 cells (Day 0 and Day 7). In addition, the alternative splicing of 13 other exons was greater than 2-fold but less than 10-fold different

between undifferentiated and neuronally differentiated P19 cells (Figure 2 and Table 1). The increased and decreased expression levels of these 26 exons were essentially consistent with the directions that were indicated by the SI d7 values. The alternations of these 26 exons were greater on Day 7 than on Day 10. These results were consistent with the ninth condition of Table 1. Taken together, the RT-PCR data showed that neuronal cell stage-specific alternative splicing occurred in 26 of 30 exons. If extrapolated to all of the candidate exons, these data suggest that 87% of the 262 candidate DAS exons were subjected to alternate splicing in a neuronal-specific manner.

Figure 3. Schematic representations of alternative splicing. Thirty exons were randomly selected from 262 DAS exons. Five of these 30 exons (*Neo1* exon 17, *Kif21b*, *Plekha5*, *Dlg3*, and *Kif1b*) are shown in this figure. The other exons are shown in Figure 2 and Table 1. The boxes and middle lines indicate exons and introns, respectively. The gray color indicates possible alternative exons. Arrows indicate the locations of the primer annealing sites. The numbers indicate the lengths of the PCR products. The sequences of the PCR products were confirmed by sequencing analyses.

We next assessed these 26 exons by RT-PCR of adult mouse brain tissue. Seven of these 26 exons were alternative splicing events that were previously undiscovered splicing patterns in mouse (*Kif1b*, *Dlg3*, *Plekha5*, *Atf2*, *Clta*, *Fam113a*, and *Zfp326*; Figure 3 and Table 1). We found a previously unknown exon, previously unknown splice sites, and previously unknown combinations of exons. Furthermore, the *Dlg3* variant was previously unknown. The other six variants were previously detected in adult mouse brains. Interestingly, the percentages of alternative variants of 17 of these 26 exons were greater than 2-fold different between brain tissue and other tissues that showed the most similar patterns to the brain tissue (Table 1). These results suggest that more than half of the DAS exons discovered in neuronal differentiated P19 cells were changed in a neuronal-specific manner in mouse brains.

GO Analyses of the Candidate Exons

To assess whether the 262 DAS exons (from a total of 236 DAS genes) were important for neuronal events, we performed GO analyses using the Biological Process category. We obtained 72 GO terms ($p\text{-value} \leq 0.01$ in the Fisher's exact test) from the 236 DAS genes and classified the terms into ten groups: 1) neuronal-related processes; 2) differentiation and development; 3) cytoskeleton and cell adhesion; 4) signaling; 5) post-translational regulation; 6) transcription; 7) cell cycle and proliferation; 8) cellular transport; 9) apoptosis; and 10) other GO terms. The neural-related processes terms were the most abundant and accounted for 20.8% of all terms. These terms were followed by the differentiation and development terms (12.5% of all terms), the cytoskeleton and cell adhesion terms (12.5% of all terms), and the signaling terms (9.7% of all terms) (Figure 4A). We next divided the 262 DAS exons into two groups. In the first group, SId7 was greater than +1.35 (DAS-up; 153 genes) and in the second group, SId7 was less than -1.35 (DAS-down; 88 genes). The percentage of neuronal-related processes terms in the DAS-up and DAS-down groups were 17.0% and 21.2%, respectively (Figure 4B). These results suggest that the protein isoforms translated from these alternatively spliced transcripts, which either included or excluded exons, were important for neuronal events.

Figure 4. GO analyses. (A) GO analyses of 262 DAS exons (236 DAS genes). Seventy-two GO terms ($p\text{-value} \leq 0.01$; Fisher's T-test) were obtained from the 236 DAS genes. These terms were categorized into 10 groups, and the percentages of all GO terms are shown. (B) GO analyses at the exon and gene expression levels. The 236 DAS genes were divided into two groups. The first group contained 153 DAS-up genes that showed increased expression on Day 7 and 88 DAS-down genes that showed decreased expression on Day 7. The 153 DAS-up genes and 88 DAS-down genes were subjected to GO analyses. In addition, the gene expression levels of 1,666 DEX-up genes were increased (2–10-fold) on Day 7 relative to Day 0 and were also decreased from Day 7 to Day 10. Furthermore, the gene expression levels of 550 DEX-down genes were decreased (2–10-fold) on Day 7 relative to Day 0 and were also increased from Day 7 to Day 10. The 1,666 DEX-up genes and 550 DEX-down were subjected to GO analyses.

In addition to the exon expression profiles, the Exon Arrays also provided gene expression profiles. The Affymetrix Expression Console calculates an expression level for each gene based on the intensities of the probe sets that are designed for exons in the whole transcript. Therefore, we analyzed the gene expression profiles and obtained DEX genes in P19 neuronal cells. The expression levels of 1,666 DEX-up genes were increased more than 2-fold and less than 10-fold from Day 0 to Day 7, and were also decreased from Day 7 to Day 10 (data not shown). The DEX-up gene group had 194 GO terms. The neuronal-related processes terms were the most abundant and accounted for 20.1% of all terms. These terms were followed by differentiation and development terms, which accounted for 18.6% of all terms (Figure 4B). Therefore, these DEX-up results were similar to the DAS results.

We next further examined the relationship between expression profiles and the GO terms. DEX-up and DAS genes were primarily associated with neuronal-related processes GO terms. These results suggested that the DAS genes and the DEX-up genes were important for neuronal events. We also obtained 550 DEX-down genes. The expression levels of the DEX-down genes were decreased more than 2-fold and less than 10-fold from Day 0 to Day 7, and were also increased from Day 7 to Day 10 (data not shown). The DEX-down gene group had 107 GO terms. By contrast to the DEX-up group, the neuronal-related processes terms accounted for only 2.8% of all terms. The cellular transport terms and apoptosis terms accounted for 11.0% and 5.6% of all terms, respectively (Figure 4B). Therefore, the GO terms of DEX-down genes showed a very different pattern than the DAS, DAS-up, DAS-down, and DEX-up genes. These data suggest that the DEX-down genes were not important for neuronal events.

Extraction of Potentially Important Exons by Pathway Analyses and Text Mining

We performed pathway analyses and text mining of the DAS genes with the MedScan text mining technology provided by Pathway Studio (Ariadne Genomics). Sixty-six of 236 DAS genes were identified as well-known genes in neuronal processes because MedScan found published scientific articles demonstrating that these genes played functional roles in neuronal cells or organs (Figures 5A and 5B). By contrast, there were no (or only a few) scientific articles linking the remaining 170 genes to neuronal cells or organs. Therefore, these 170 genes were categorized as genes with no known neuronal functions. These results confirmed the GO analyses and further demonstrated that many of the DAS genes were important for neuronal events. Moreover, 49 of the 236 DAS genes had identified isoforms or splicing variants of transcripts in published scientific articles (Figure 5B). Thirty-four genes had both known neuronal functions and characterized splicing variants (Figure 5A and B). Among these 34 DAS genes, the exons of 15 genes agreed with the published variants (Table 2). Furthermore, different functions of the alternative isoforms were published for nine of these 15 genes (Table 2).

In the GO analyses (Figure 4), DEX-up genes were important for neuronal events and DEX-down genes showed no specific relation to neuronal events. We extracted 279 cell process terms closely related to the DEX-up and the DEX-down genes from neuronal cell, neuronal tissue, and neuronal organ literature using the text mining and Pathway Studio databases (Figure 5C). Ninety terms were subtracted because they were found in both the DEX-up and DEX-down groups. We assumed that the remaining 189 cell process terms were essentially

responsible for neuronal events in differentiated P19 cells and considered these terms to be neuronal cell-specific processes. We next extracted the biological relationships between these 189 cell processes and the 170 DAS genes with no known neuronal functions. Forty-eight of these 170 genes were linked to these cell processes (Figure 5A). Therefore, these 48 genes are potentially important because neuronal-specific isoforms generated by alternative splicing may play essential neuronal roles that have not yet been discovered. Furthermore, 11 of these 48 genes were involved in cell cycle-related events such as G1 and/or S phase-related cell processes (Figure 6). These results are potentially interesting because cell proliferation and cell differentiation are very closely related.

Figure 5. Pathway analyses and text mining results. (A) A flow chart representing how well-studied alternative exons and potentially important exons were extracted. Pathway Studio was used to determine whether there were published scientific reports showing that any of the DAS genes played functional roles in neuronal cells or organs. Of the 236 DAS genes, 66 genes had known neuronal functions. The approach for assessing the remaining 170 genes is described in Figure 5B. Of these 66 genes, 34 genes (40 DAS exons) were reported to have splicing variants or isoforms. These reported variants were compared with the probe set ID sequences of the 34 genes (40 exons). (B) Cell processes were used to assess the 170 genes with no known neuronal functions. The cell processes from the pathway analyses of the DEX-up and DEX-down genes were used (see Figure 4C). The orange and yellow colors indicate the numbers of biological processes from DEX-up genes and the yellow and blue colors indicate the numbers of biological processes from DEX-down genes. Because DEX-up genes were important for neuronal events and the DEX-down genes were not (Figure 4), we predicted that the 189 biological processes that were specific to the DEX-up genes were important for neuronal differentiation. Of the 170 genes with no known neuronal functions (see Figure 5A), 48 genes were matched with the 189 biological processes that were specific to the DEX-up genes. (C) The genes that were linked with neuronal functions. The 66 genes with known neuronal functions are indicated in orange and purple colors. The 48 genes that were linked with the 189 processes specific to the DEX-up genes are indicated in yellow and green colors. The 148 genes that were not linked with the DEX-up gene processes are indicated in white and blue colors. The 49 genes with reported variants or isoforms are indicated in purple, green, and blue colors.

Informatics and Experimental Analyses of Splicing Isoforms

In addition to the gene level analyses described above, we also performed informatics analyses at the exon level. Forty-nine of the 236 DAS genes were identified as isoforms or splicing variants of transcripts in published scientific articles (Figure 5C). Thirty-four genes had both known neuronal functions and characterized splicing variants (Figures 5A and B). Among these 34 DAS genes, the exons of 15 genes agreed with the published variants (Table 2). Furthermore, different functions of the alternative isoforms were published for nine of these 15 genes (Table 2). These nine genes with alternative isoforms that have different functions might be important for neuronal events. Therefore, we analyzed one of these nine genes, *Gnao1*, with semi-quantitative RT-PCR experiments. The RT-PCR results and the SI values indicated that the *Gnao1* B isoform (189 nt) was expressed in undifferentiated P19 cells and that the *Gnao1* A isoform (124 nt) was expressed in P19 neuronal cells (Tables 1 and 3). These data are consistent with a previous report showing that the *Gnao1* A isoform, but not the *Gnao1* B isoform, is required for light responses in retinal bipolar cells (30).

Of the 49 DAS genes previously identified as isoforms or splicing variants of transcripts in published scientific articles, 15 were also found in a group of 85 functional genes (Figure 5C). We analyzed the splicing of one of these 15 genes, *Abi2*, with RT-PCR experiments (Table 1). Detailed expression analyses of *Abi2* splicing variants have not yet been performed. However, the RT-PCR results and the SI values indicated that a skipping isoform (149 nt) of *Abi2* was expressed in undifferentiated P19 cells and that an inclusion isoform (329 nt) was expressed in P19 neuronal cells (Table 2). Interestingly, there is a published article about the neuronal functions of the *Abi2* gene, which found that *Abi2* is involved in learning and memory (31). To test whether *Abi2* splicing is related to these higher brain functions, we investigated alternative splicing of *Abi2* in brains. The inclusion isoform was expressed at higher levels in the frontal cortex than in other neuronal tissues. These preliminary results implied that neuronal regulation of *Abi2* alternative splicing might be important for higher brain functions.

DISCUSSION

For exon array studies, it is essential to validate that alternative exons actually exist in cells with RT-PCR experiments. Our semi-quantitative RT-PCR results found that 87% of the 262 DAS exons were altered in P19 neuronal cells (Table 1). This high validity suggests that our filtering conditions successfully and efficiently extracted DAS exons from Exon Array signals. Another important aspect of exon array studies is that the filtering conditions should be easy to modify. Our filtering conditions consisted of simple parameters and annotations that were easily modifiable. For example, if we wanted to obtain more specific potential DAS exons, we could increase the ABS_SId7 threshold in the sixth condition (Table 1). We could use a threshold of ≥ 3.0 rather than ≥ 1.35 . It is likely that higher ABS_SI thresholds would result in large alternative splicing differences in the RT-PCR experiments (Table 1). As shown in Figure 1A, 40–50% of the probe sets in the higher ABS_SId7 group indicated alternative exons in the UCSC BLAT search. We assumed that there were several alternative splicing events in DAS exons that resulted in high ABS_SI values. Indeed, the DAS exons were validated by RT-PCR to be alternatively spliced in a neuronal-specific manner. Therefore, while this threshold can be

varied, we believe that a threshold of ≥ 1.35 was an appropriate filtering condition. The approximation curve showed that the percentage of the predicted alternative exons decreased in the area with high ABS_SId7 values and the number of non-alternative exons plateaued around 1.35 (Figure 1A). This was because several of the potential DAS exons already accumulated with the ≥ 1.35 threshold. Thus, we believe that the inflection point between the decreasing range and the plateau state is a suitable ABS_SI threshold (Figure 1A).

In addition to the efficient extraction of DAS exons using simple parameters and annotations, we also suggest using accessible software such as the Expression Console and Microsoft Excel even though we generated a program to compare SI values of neighboring probe sets. Open access homology search tools such as NCBI BLAST and UCSC BLAT are useful for predicting alternative exons. These applications save time and money when performing exon array analyses. For all these reasons, we believe that our extraction method provides an efficient way to simply extract DAS exons. Therefore, our methods will be useful for projects that are attempting to perform exon array analyses. In addition, our method provides a way to comprehensively analyze alternative splicing events.

In this study, we found seven previously undiscovered splicing patterns among 30 randomly selected exons from the 262 DAS exons (Figure 2 and Table 1). These results suggest that there are several undetermined alternative splicing events. If we extrapolate our data (7 of 30 exons), it is possible that approximately 23% of the probe sets that were removed by the alternative splicing prediction searches (the eighth condition of the filtering) had novel splicing patterns. Exon and/or intron scoring with exonic splicing enhancer and exonic splicing silencer may accurately predict DAS exons. Thus, we believe that this approach may be effective when attempting to find aberrant splicing events, which are frequently observed in cancer cells. Informatics analyses showed that only 49 of the 236 DAS genes were previously reported as having alternative splicing variants (Figure 5). Although exon level annotations are a relatively new approach, it is likely that simply searching for splicing isoforms is not sufficient to comprehensively assess alternative splicing. Moreover, there are no assembled databases that assess the functional roles of splicing isoforms even though there are several databases that show the functional roles of genes and proteins. However, expression profiles of alternative splicing events are more proportional to proteomics than standard gene expression profiles. In addition, the expression profiles of alternative splicing events are starting to accumulate in databases. Therefore, informatics analyses at the exon level will become more important as better tools become available.

We found that DAS genes had identified isoforms or splicing variants of transcripts in published scientific articles. Moreover, 34 of these 49 genes were known to have functional roles in neuronal cells or organs. Furthermore, different functions of the alternative isoforms were published for nine of these 34 genes (Table 2). Gnao1 is one of these nine genes and the Gnao1 A isoform is required for the neuronal response to light (30). The Gnao1 B isoform (189 nt) was expressed in undifferentiated P19 cells and the Gnao1 A isoform (124 nt) was expressed in P19 neuronal cells (Table 1). Furthermore, Gnao1 A isoform was abundant in brain tissue. Therefore, Gnao1 alternative splicing is likely to be important for neuronal differentiation. Abi2 was one of the 49 genes that were known to have functional roles in neuronal cells and organs. In addition, Abi2 was categorized as one of the 85 functional genes. It is unknown whether the different Abi2 isoforms play different functional roles. A skipping isoform (149 nt) of Abi2 was expressed in undifferentiated P19 cells and an inclusion isoform (329 nt) was expressed in P19 neuronal cells (Table 1). The inclusion isoform was expressed at higher levels in the frontal

cortex than in other neuronal tissues. We assume that alternative splicing regulation of *Abi2* is important for higher brain functions because a previous study showed that *Abi2* is involved in learning and memory (31). Based on these *Abi2* data, we believe that the group of 85 functional genes is the most important group for future investigations because these genes are mostly uncharacterized in neuronal cells or organs.

Informatics analyses showed that many of the DAS and DEX-up genes were important for neuronal events. These results suggested that our extraction of DAS exons from the exon array signals used appropriate filtering conditions and was successful. Based on the GO biological process terms associated with the DEX-up genes, we believe that these genes are responsible for neuronal events in differentiated P19 neuronal cells. On the other hand, the GO terms associated with the DEX-down genes were not neuronal-related terms. It is easy to speculate that the protein products of DEX-down genes show reduced expression in P19 neuronal cells. Reductions or disruptions of DEX-down protein products do not permit these proteins to play any functional roles in the differentiated cells. Therefore, even if the reductions or disruptions of DEX-down protein products are important for cellular events in P19 neuronal cells, it is difficult to demonstrate that disruptions of expression contribute to biological events. Recently developed reverse genetic techniques such as RNA silencing may help to demonstrate whether there is negative linkage between a biological event and disruption of expression levels as seen with the DEX-down genes. Regardless, our GO analyses demonstrated that DEX-up gene-related functions were important for the biological events during neuronal differentiation of the P19 cells. Therefore, we searched for links between the 189 cell process terms from the pathway analyses of the DEX-up genes and the 170 DAS genes with no known functions in neuronal cells or organs (Figure 5A). Forty-eight of these 170 DAS genes were linked to these cell processes, and 11 of these 48 DAS genes play important roles in the G1/S transition. Therefore, alternative splicing of these 11 genes is likely to be important for neuronal differentiation because cell proliferation and cell differentiation are very closely related (Figure 6). There are still several unknowns in alternative splicing research. Based on the results in this chapter, we believe that our informatics approach provides a basis to determine the potentially important DAS exons.

Alternative splicing contributes to protein diversity in higher eukaryotes. It is difficult to obtain comprehensive protein expression profiles. However, the expression profiles of alternatively spliced transcripts can be determined from exon array analyses. Furthermore, the expression profiles of alternatively spliced transcripts are more proportional to proteomics than gene expression profiles. There are several open access databases for functional analyses of genes and proteins, but there are no databases for functional analyses of alternative isoforms. In this study, we converted 262 DAS exons into 236 DAS genes and then applied GO analyses and pathway analyses (Figures 4 and 5). Because there are no databases for functional analyses of alternative splicing isoforms, we analyzed whether any alternative splicing variants of the 236 DAS genes were previously reported by using a text mining method (Figure 5). Forty-nine of the 236 DAS genes had known alternative splicing variants and 34 of these 49 genes played functional roles in neuronal cells or organs. We confirmed that 13 DAS exons among the 34 DAS genes were previously reported (Table 2). Although 34 genes played known functional roles in neuronal cells and organs, there were many more genes (170) that were uncharacterized in neuronal cells and organs. Therefore, our informatics approach used to assess these 170 DAS genes provides a basis for future studies to analyze previously uncharacterized alternative splicing events.

Figure 6. Pathway analyses of the 48 DAS genes that were linked to the biological processes specific to the DEX-up genes. Pathway Studio was used to link the 170 DAS genes with no known neuronal functions to the 189 biological processes that were specific to the DEX-up genes (see Figure 5A). The 48 DAS genes and their linked biological processes were shown above. Many of these genes had known cell cycle functions (indicated by orange and red colors) and specifically functions related to G1 and/or S phase (indicated by red color).

The 34 DAS genes (40 DAS exons) found with both known neuronal functions and characterized splicing variants or isoforms (see Figure 5A). The probe set ID sequences of the 40 DAS exons and the published variants of these genes were compared to determine whether the sequences and the variants were the same isoforms. In addition, published reports describing different functions of the different isoforms were searched.

B. J. Blencowe stated that there are four layers of gene expression regulation including the transcriptional network and the alternative splicing network (10). In this chapter, we obtained gene expression profiles and expression profiles of alternatively spliced transcripts. These profiles provided important information about the key regulatory factors and their potential targets in the transcriptional and the alternative splicing networks. Approximately 20 genes that were related to RNA processing were observed in the DEX-up group of genes and 14 of these 20 genes were DAS genes. These genes may play key roles in regulating neuronal alternative splicing. For instance, a previous report found that the exon-inclusion activities of RBM9, which was one of these DAS genes, were reduced in its isoform. Our results also suggested that cell cycle-related genes were important for neuronal events (Figure 6). A few of the cell cycle-specific splicing regulators were previously described. We previously reported that SRp38/NSSR1, which was detected during neuronal differentiation in P19 cells (21). SRp38/NSSR1 represses splicing via dephosphorylation in an M-phase-specific manner. In addition, nucleophosmin is also a cell cycle-dependent splicing regulator. Nucleophosmin is phosphorylated during the G1/S transition and functions as a splicing repressor. We believe that future studies should focus on these splicing regulators and their potential targets to clarify alternative splicing networks during neuronal differentiation of P19 cells.

Chapter 22

IDENTIFICATION OF GENUINE ALTERNATIVE SPLICING VARIANTS FOR RARE OR LONG-SIZED TRANSCRIPTS

Seishi Kato*

Research Institute, National Rehabilitation Center for Persons with Disabilities,
Tokorozawa, Japan

ABSTRACT

Only sequence analysis of full-length transcripts can identify genuine alternative splicing variants. However, it was difficult to obtain full-length cDNAs for rare or long-sized transcripts. Recently, we have developed a powerful method, named a vector-capping method, to construct a size-unbiased full-length cDNA library containing rare or very-long-sized cDNA clones with >10kbp inserts. The characteristic of the full-length cDNA contained in this library is that the intactness of the 5'-end capped site sequence of the cDNA can be assured by the presence of an additional dG at its 5' end. Since this full-length cDNA is derived from a single mRNA, this library enables us to perform in-depth analysis of genuine alternative splicing variants. Using the vector-capping method, we prepared full-length cDNA libraries from human retina-derived cell lines and analyzed the full sequence of the clones. As a result, we found many novel alternative-splicing variants for rare or long-sized transcripts. In this chapter, I show the examples of these variants including very-long-sized transcripts with >7kbp that were identified by us for the first time.

1. INTRODUCTION

The Human Genome Project revealed that the human genome seems to encode only 20,000~25,000 protein-coding genes (International Human Genome Sequencing Consortium,

* Corresponding Author's Email: kato-seishi@rehab.go.jp (National Rehabilitation Center for Persons with Disabilities, 4-1 Namiki, Tokorozawa, Saitama 359-8555, Japan).

2004). The analysis, including the evolutionary conservation, further cut the number of protein-coding genes to ~20,500 (Clamp et al., 2007). This number was unexpectedly small to understand the function of genes underlying the complex biological system in the cell. This issue has been solved by the discovery of diverse transcript variants for each gene. The recent research showed that diverse variants are produced from a single gene locus due to alternative promoter usage (Kimura et al., 2006), alternative splicing (AS) (Modrek et al., 2001), and alternative polyadenylation (Beaudoing et al., 2000). Initially, these variants were identified by mapping of expressed sequence tags (ESTs) to the genome. Recently, a new high-throughput sequencing technology such as mRNA-seq was applied to in-depth sequencing analysis of mRNAs isolated from various tissues and cell lines. These analyses revealed that more than 90% of human genes undergo AS (Wang et al., 2008; Pan et al., 2008).

Since the AS events vary between tissues and between developmental stages, each AS variant should be involved in the regulation of tissue-specific or cell-specific development. To fully understand the relationship between the genetic information encoded by the genome and the biological function of the cell, it is necessary to identify all transcripts including a full set of AS variants. One trial to achieve this purpose was an ENCODE project (ENCODE Project Consortium, 2011). This project adopted tiling DNA microarrays, RNA-seq, cap-analysis of gene expression (CAGE), and paired-end diTag (PET) to determine exonic regions, transcription start sites (TSSs), splice junctions, transcript 3' ends, and polyadenylation sites (Djebali, 2012). However, these protocols produce only partial sequence showing the presence of each site. Patterns of AS and alternative cleavage and alternative polyadenylation were found to be strongly correlated across tissues (Wang et al., 2008). This means that we need to know the precise combination of these alternative sites to determine the correlation between them.

To know the combination of multiple variation sites in a single transcript, the full sequence of the full-length transcript is required. The analysis of full-length transcripts can be achieved by obtaining the corresponding full-length complementary DNA (cDNA). Large-scale sequencing analyses of full-length cDNA clones were carried out using full-length cDNA libraries synthesized with the oligo-capping method (Takeda et al., 2006; Wakamatsu et al., 2009). These analyses identified a large number of AS variants including alternative TSSs.

The conventional methods for synthesizing full-length cDNAs have the following problems: (i) inability to determine whether or not the cDNA starts from a true TSS, (ii) loss of some clones due to restriction enzyme treatment during a cDNA synthesis process, (iii) difficulty in synthesizing long-sized cDNAs. Recently, we have developed a novel method, named a vector-capping method, to overcome these problems (Kato et al., 2005; Kato et al., 2011). Using this method, we prepared full-length cDNA libraries from human retina-derived cell lines. By the large-scale sequencing analysis of these libraries, we identified a lot of novel AS variants (Kato et al., 2005; Oshikawa et al., 2008; Oshikawa et al., 2011). In this chapter, I describe the examples of novel splicing variants for rare or long-sized genes we identified, and I would like to emphasize the importance of identifying a genuine AS variant derived from a single mRNA using full-length cDNA.

2. SYNTHESIS OF FULL-LENGTH cDNA USING THE VECTOR-CAPPING METHOD

We started our investigation 20 years ago by focusing on how to obtain whole human proteins. The strategy we took was to collect all proteins as a form of cDNA. At that time, the Human Genome Project had been launched and one of the projects was to analyze ESTs. However, ESTs composed of cDNA fragments were not suitable to obtain proteins. To achieve our purpose, we needed to obtain a full-length cDNA that contains an intact open reading frame (ORF) to produce the encoded protein. Thus, we developed a novel method to synthesize full-length cDNA based on replacing the cap structure of mRNA by a DNA-RNA chimeric oligonucleotide (Kato et al., 1994). This method enabled us to effectively synthesize full-length cDNAs, but it had drawbacks; it required a lot of mRNA and many reaction steps.

When improving this method, we succeeded in developing the vector-capping method shown in Figure 1 (Kato et al., 2005; Kato et al., 2011). Its process is very simple; the first-strand cDNA is synthesized using a vector primer, and then the vector-cDNA conjugate is circularized. The development of this method is attributed to the discovery of an unexpected reaction: the 3' end of the first-strand cDNA can be ligated to the 5' end of the vector primer using "RNA ligase". Furthermore, we found that the full-length cDNA possesses an additional dG at the 5' end. This additional dG is derived from dC that added to the 3' end of the first-strand cDNA by terminal deoxynucleotidyl transferase activity of reverse transcriptase only when the template mRNA has a cap structure. Thus, the presence of the additional dG at the 5' end assures the intactness of the 5'-end capped site sequence of the cDNA.

Figure 1. Schematic procedure for the vector-capping method. Several micrograms of total RNA is enough as a starting material. A vector primer has an approximately 60-nucleotide dT tail. The EcoRI digestion step can be omitted. Since the full-length cDNA vector has an SV40 promoter, the encoded protein can be produced in the mammalian cells by introducing the vector into the cells.

The full-length cDNA library constructed using the vector-capping method has the following advantages compared with those by conventional methods:

- (i) the library is composed of genuine full-length cDNA clones of > 95% content,
- (ii) we can identify full-length cDNA by the presence of an additional dG at the 5' end,
- (iii) artificial mutation or deletion seldom occurs because the procedure contains neither PCR nor the restriction enzyme treatment step,
- (iv) the library contains full-length clones for rare or long-sized genes,
- (v) we can easily identify the cDNA for an antisense gene due to the use of the vector primer.

Thus, the resulting cDNA library seems to provide us with the full-length cDNA clones ideal for identifying the alternative TSS, AS, and alternative polyadenylation.

3. ANALYSIS OF FULL-LENGTH cDNA CLONES

3.1. Retina-Derived Full-Length cDNA Libraries

We have been searching for genes responsible for retinitis pigmentosa, which is the major cause of visual impairment among patients visiting our center. To identify a novel candidate gene causing this disease, we identified genes specifically expressed in the retina by analyzing the full-length cDNA libraries that were constructed from human retinal pigment epithelium cell line ARPE-19 and human retinoblastoma cell line Y79 using the vector-capping method (Kato et al., 2005; Oshikawa et al., 2008; Oshikawa et al., 2011). We randomly picked up 100,000 clones from each library and stored them as glycerol stocks. By sequencing the 5' end of approximately 24,000 clones from each library, we identified a total of 39,643 full-length cDNA clones that were classified into 7,067 genes (Oshikawa et al., 2011). In this section, I describe the examples of novel AS variants obtained from the above libraries. Most of full-length clones and the other full-length cDNA libraries remain not fully analyzed: ARPE-19, 52,800 clones; Y79, 52,800 clones; embryonal pluripotent carcinoma cell line NT2/D1, 76,800 clones; human testis, 76,800 clones. If researchers are interested in particular genes, they may find new AS variants by full sequencing of those clones. All clones are available from RIKEN BioResource Center DNA Bank (<http://dna.brc.riken.jp/en/NRCDhuman.html>).

3.2. Characterization of Eye-Specific Genes

3.2.1. Aryl Hydrocarbon Receptor Interacting Protein-Like 1 (*AIPL1*)

Since retinoblastoma cell line Y79 is derived from cone progenitor cells (Xu et al., 2009), Y79 cells expressed various photoreceptor-specific genes. One of abundant eye-specific genes found in our Y79 full-length cDNA libraries was *AIPL1*. *AIPL1* has been identified as a gene responsible for Leber congenital amaurosis (LCA), a severe early-onset retinopathy that leads to visual impairment in infants (Sohocki et al., 2000).

Fifteen clones (C1-C15) encoding AIPL1 were fully sequenced, and their exon-intron structures were determined as shown in Figure 2. Since TSSs were distributed within the range of position -14 to position 13, the same promoter seemed to be used. We identified seven AS variants by the shift of a splicing site, skipping of exon 3, and the alternative use of a polyadenylation signal. The encoded proteins were classified into five isoforms: 384-amino acid (aa) isoform (V1 and V4, 9 clones); 345-aa isoform (V3, 2 clones); 321-aa isoform (V2 and V5, 2 clones); 270-aa isoform (V6, 1 clone); 262-aa isoform (V7, 1 clone). The difference between V1 and V4 and the difference between V2 and V5 were due to the alternative use of the polyadenylation signal. V3 showed the 58-bp downstream shift of the 3' splice site of exon 1 (designated by #7 in Figure 2), resulting in the shift of the initiation codon of the longest ORF from exon 1 to exon 2. This shift causes the loss of the N-terminal 39-aa residues. V2 and V5 lacked exon 3, resulting in the 63-aa deletion from the middle part of the protein. V6 and V7 lacked exon 6 because of the shift of the polyadenylation site, resulting in the deletion of the C-terminal 114-aa residues. Furthermore, V7 showed the 24-bp downstream shift of the 5' splice site of exon 4 (designated by #8), causing the corresponding 8-aa deletion. It should be noted that the Y79 cell-derived transcripts showed five single nucleotide polymorphisms (#1, #2, #4, #5, #6) and 2-bp deletion (#3). As a result, the clones were classified into two haplotypes, and their allelic origin was identified. Half of the clones (C3, C7, C9, C11, C12, C13, C14) were assigned to one haplotype.

The identified variants were compared with RefSeq in GenBank provided by the National Center for Biotechnology Information (NCBI), which is a collection of taxonomically diverse, non-redundant and richly annotated sequences representing naturally occurring molecules of DNA, RNA, and protein (Pruitt et al., 2009). Three RefSeqs were constructed as the transcripts of an *AIPL1* gene. RefSeq1 and RefSeq2 correspond to V1 and V2, respectively. Our collection did not contain the clone corresponding to RefSeq3 that is an AS variant skipping exon 2. In NCBI's GenBank, 13 sequences except for our 14 sequences were registered as *AIPL1* mRNA with an ORF. However, these mRNA sequences had no polyadenylation signal, whereas our clones had a canonical polyadenylation signal, AATAAA (V1-V6) and AGTAAA (V7) followed by a poly(A) tail. The mRNA sequences without a polyadenylation signal were terminated before an A-stretch (A₁₅) at position 1386 of RefSeq1 or an A-rich region (A₆CA₄CA₄CA₅) at position 2131. These clones seem to have been synthesized by priming of the oligo(dT) primer to these A-stretch sites during the first-strand cDNA synthesis. Of these 13 mRNAs, five clones correspond to V1, two clones to V2, and one clone to V6. The remaining five clones were novel variants, suggesting that there would be more variants for *AIPL1* transcripts to be identified.

AIPL1 has been reported to interact with various proteins including NUB1 (Akey et al., 2002), FAT10, FAT10nylated protein, UBA6 (Bett et al., 2012), and the catalytic subunit (alpha) of rod cGMP phosphodiesterase (PDE6A) (Kolandaivelu et al., 2009). AIPL1 is necessary for the proper assembly of functional rod PDE6 subunits (Kolandaivelu et al., 2009) that is a key phototransduction enzyme. AIPL1 is composed of three functional domains: an FKBP-like prolyl peptidyl isomerase (FKBP) domain, a tetratricopeptide (TPR) domain, and Pro-rich domain (PRD).

Figure 2. The exon-intron structure of alternative splicing variants for *AIPL1*. Fifteen clones (C1-C15) were classified into seven variants (V1-V7). The relative position of a transcription start site was indicated on exon 1. Arrowheads represent the following sequence variations: #1, SNP (A>G); #2, SNP (A>G); #3, 2-nt deletion (AA>--); #4, SNP (A>G); #5, SNP (A>G); #6, SNP (C>T); #7, downstream splicing site shift (58 bp); #8, downstream splicing site shift (24 bp). RefSeq1, RefSeq2, and RefSeq3 correspond to GenBank Accession No. NM_014336.3, NM_001033054.1, and NM_001033055.1, respectively. Our clones correspond to AB593062.1 - AB593067.1.

V3 encodes an isoform lacking the N-terminal 39-aa residues whose function is unclear. V6 and V7 encode an isoform lacking the C-terminal 114-aa residues corresponding to the PRD carrying a chaperone activity (Li et al., 2013). This isoform might lose function as a chaperone, because the Trp278X mutant lacking the C-terminal 107-aa residues causes LCA (Sohocki et al., 2000). V2 and V5 encode an isoform lacking the FKBP domain. To elucidate why these isoforms lacking a functional domain are produced in the cell, it is necessary to know the role of each isoform in the *AIPL1* regulation system by investigating their localization in the cell or binding activity with other proteins. Although the expression level of each minor variant is low, the total level of minor variants reaches the same level as main variants (V1 and V4), suggesting that isoforms encoded by these minor variants play their own roles in the *AIPL1*-related system. Since the EST database in GenBank (dbEST) contains novel variants, we would find more novel variants by analyzing the full-length cDNA libraries.

3.2.2. LIM Momeobox 3 (*LHX3*)

The Y79 libraries contained many clones encoding various eye-specific transcription factors. A transcription factor *LHX3* is a member of a large protein family that carries a LIM domain, a Cys-rich zinc-binding domain, and is required for pituitary development and motor neuron specification. Two variants encoding human *LHX3* (isoform a and isoform b) have been cloned from pituitary cDNA libraries (Sloop et al., 1999), and they were adopted as RefSeq for *LHX3* genes. The mutation of this gene caused combined pituitary hormone deficiency (CPHD) (Netchine et al., 2000). There is no report for *LHX3* expressed in the eye except for ESTs obtained from eye and pineal gland libraries in dbEST.

Eight clones for *LHX3* were obtained from the Y79 cDNA libraries and four variants were identified as shown in Figure 3. Five clones designated by V1 encoded a 397-aa isoform a. V2 using an alternative promoter had a different exon 1 from V1 and encoded a 402-aa isoform b. As a result, the N-terminal 25-aa sequence of isoform a was different from the N-terminal 30-aa sequence of isoform b. V3 was a novel variant containing an unspliced intron between exon 2 and exon 3, resulting in shortening of the first ORF followed by a longer ORF. The upstream short ORF encoded the N-terminal 89-aa sequence of the isoform a and the downstream long ORF encoded the C-terminal 264-aa sequence of isoform a. V4 using another promoter had a novel exon 1, and encoded a novel 386-aa isoform whose N-terminal 15-aa sequence was different from those of isoform a and b.

Figure 3. The exon-intron structure of alternative splicing variants for *LHX3*. Eight clones (C1-C8) were classified into four variants (V1-V4). The relative position of a transcription start site was indicated on exon 1. RefSeq1 and RefSeq2 correspond to GenBank Accession No. NM_178138.4 and NM_014564.3, respectively. Our clones correspond to AB593042.1 - AB593055.1.

V1 and V2 correspond to RefSeq1 and RefSeq2, respectively. V3 and V4 are novel variants. In GenBank two mRNA sequences containing ORF were registered except for our six sequences. These mRNAs correspond to isoform a and isoform b that were cloned from human pituitary cDNA libraries (Sloop et al., 1999). These two sequences had no polyadenylation signal maybe due to the use of a random primer in synthesizing cDNA. The dbEST contained 13 sequences: nine from eye, two from pineal gland, and two from brain. All sequences lacked

a sequence corresponding to exon 1. The cDNA libraries used for cloning these ESTs were prepared using conventional methods that contained a NotI or XhoI treatment step. Since the sequence of the full-length cDNA contained NotI and XhoI sites, the fragmentation of synthesized cDNA might occur. Although dbEST contained many ESTs isolated from the Y79 full-length cDNA libraries prepared using the oligo-capping method, there was no EST for *LHX3* in spite of an abundant gene. This was explained by the presence of an SfiI site in the *LHX3* gene, because the oligo-capping protocol contained a step using linkers with the SfiI site (Suzuki and Sugano, 2001).

LHX3 has two LIM domains, a homeodomain, and a C-terminal LHX3-specific domain. Three isoforms for human LHX3 (isoform a, isoform b, short isoform) have been reported (Sloop et al., 2001). Isoforms a and b differ in their N-terminal sequence. The N-terminal sequence of isoform b has been shown to inhibit the binding of LHX3 to DNA. Furthermore, isoform a produced a 264-aa short isoform starting at Met-134 and thus lacking LIM domains. This short isoform showed a transcription factor activity owing to the downstream region including a homeodomain. Interestingly, the longest ORF of the novel variant V3 encoded this short isoform. It is also interesting whether the N-terminal sequence of the novel isoform encoded by V4 affects the activity of LHX3. In the pituitary gland, the expression pattern of V1 and V2 differed between cell lines, suggesting that these variants play a different role in the regulation of gene expression during development of each cell type (Sloop et al., 2001). The role of these variants in development of the retina remains to be solved.

3.2.3. Neural Retina-Specific Leucine Zipper Protein (NRL)

NRL is a basic motif-leucine zipper transcription factor that plays an essential role in the differentiation of photoreceptor cells (Swaroop et al., 1992). The Y79 libraries contained seven clones encoding NRL, which were classified into five variants as shown in Figure 4. V1 corresponded to RefSeq1, and V2 had a shortened 3'-untranslated region (3'-UTR) due to the alternative use of a polyadenylation signal. V3, V4, and V5 used an alternative promoter located between exon 1 and exon 2. Although the 3'-end splice sites of a new exon 1 of these three variants were slightly different, these variants had the same ORF in exon 2, which encoded a 98-aa sequence starting from Met-140 in the isoform encoded by V1. When the expression vectors of these variants were introduced into cultured cells, the corresponding 98-aa short protein was produced (unpublished data). Since this short isoform lacked a minimal transactivation domain (Friedman et al., 2004), it showed no transcriptional activity as expected. The Leu zipper domain has been reported to interact with a CRX homeodomain (Mitton et al., 2000). The short isoform carrying only the Leu zipper domain may be involved in the regulation of complex formation through this domain.

GenBank contained three mRNAs (one corresponding to V1 and two to V2) except for the six sequences we registered. The dbEST contained six V4 sequences and one V5. Although one research group cloned the cDNA corresponding to V4, the authors could not judge whether it was a full-length or truncated one (Wistow et al., 2002). Like this case, when only one cDNA different from known ones is cloned, it is difficult to judge its intactness. Even in such case, our clone can be identified to be a full-length clone by the presence of an additional dG at the 5' end. Since the V1 sequence had SfiI sites, the Y79 cDNA libraries prepared using the oligo-capping method missed cloning the full-length cDNA for *NRL*.

Figure 4. The exon-intron structure of alternative splicing variants for *NRL*. Seven clones (C1-C7) were classified into four variants (V1-V5). The relative position of a transcription start site was indicated on the first exon. RefSeq correspond to GenBank Accession No. NM_006177.3. Our clones correspond to AB593102.1 - AB593104.1.

3.2.4. *OTX2 Antisense RNA 1 (OTX2-AS1)*

Our libraries contained many novel non-coding RNAs including rare variants. As an example of an eye-specific non-coding RNA, we obtained five clones for *OTX2-AS1* from the Y79 libraries. These clones showed a variety of structures as shown in Figure 5. The length of cDNA varied from 303 bp of V2 to 2900 bp of V3 and the splicing pattern varied from clone to clone. Only a part of exon 1 was shared within all variants. The sequences in dbEST are also rich in variety. *OTX2-AS1* is a gene transcribed in the opposite direction at the upstream region of the locus of orthodenticle homeobox 2 (*OTX2*) that is a transcription factor involved in the development of brain and sensory organs (Alfano et al., 2005). Our Y79 libraries also contained three clones for *OTX2*, each of which is an AS variant (data not shown). The exon 1 of a variant of mouse *Otx2-as1* overlapped with the antisense strand of the exon 1 of *Otx2* (Alfano et al., 2005), but there was no human variant whose exon 1 overlapped to *OTX2*. Since all ESTs for *OTX2-AS1* in dbEST were obtained from retina cDNA libraries, this gene might be involved in the development of retina. The presence of diverse AS variants implies the complex regulation system by this gene.

Figure 5. The exon-intron structure of alternative splicing variants for *OTX2-AS1*. Five clones (C1-C5) were classified into four variants (V1-V4). The relative position of a transcription start site was indicated on the first exon. RefSeq correspond to GenBank Accession No. NR_029385.1. Our clones correspond to AB593038.1 - AB593041.1.

3.3. Characterization of Long-Sized Genes

3.3.1. Very-Long-Sized Genes

We succeeded to clone 82 full-length cDNAs with >7kbp from the libraries prepared using the vector-capping method (Oshikawa et al., 2008; Oshikawa et al., 2011). The ARPE-19 libraries contained full-length cDNA clones encoding golgin B1 (*GOLGB1*, 11.2kbp), NEDD4 binding protein 2 (*N4BP2*, 9.7 kbp), acetyl-CoA carboxylase alpha (*ACACA*, 9.5 kbp), filamin B, beta (*FLNB*, 8.0-9.4 kbp), filamin C, gamma (*FLNC*, 9.2 kbp), spectrin, beta, non-erythrocytic 1 (*SPTBN1*, 8.4 kbp), filamin A, alpha (*FLNA*, 8.2 kbp), collagen, type V, alpha 1 (*COL5A1*, 8.1 kbp), spectrin, alpha, non-erythrocytic 1 (*SPTAN1*, 7.8 kbp), fibronectin 1 (*FN1*, 7.8 kbp), myosin, heavy chain 9, non-muscle (*MYH9*, 7.4 kbp), and agrin (*AGRN*, 7.3 kbp). The Y79 libraries contained full-length cDNAs encoding Dmx-like 1 (*DMXL1*, 12.8 kbp), *GOLGB1* (11.1 kbp), SEC16 homolog A (*SEC16A*, 9.0 kbp), *FLNA* (8.4 kbp), eyes shut homolog (*EYS*, 8.0 kbp). Out of these genes, four genes having multiple AS variants were selected and their structures were analyzed below.

3.3.2. Golgin B1 (*GOLGB1*)

GOLGB1 is a huge integral membrane protein located in Golgi, originally named giantin (Linstedt et al., 1993). Two research groups cloned approximately 10-kbp cDNA encoding a protein that reacts with autoantibody contained in sera of patients with chronic rheumatism: mRNA1, 10,295-bp cDNA encoding 3,225-aa protein (Sohda et al., 1994); mRNA2, 10,300-bp cDNA encoding 3,259-aa protein (Seelig et al., 1994). These clones were not derived from a single mRNA. The full sequence was constructed by combining the sequences of cDNA fragments. Thus, it is doubtful whether the sequence reflects the true structure of the AS variant.

Our libraries contained two full-length cDNA clones for *GOLGB1* (V1 from ARPE-19, 11.2 kbp; V2 from Y79, 11.1 kbp). The exon-intron structures of the above four clones were different as shown in Figure 6. In GenBank, RefSeqs seem to be constructed by referring to registered mRNAs including our clones: RefSeq1 to V1; RefSeq2 to mRNA2; RefSeq3 to mRNA1; RefSeq4 to V2. Although exon 1 was shared within all clones, they were all different AS variants encoding the protein with the different number of aa residues. In V1 and mRNA1, the 28-bp downstream shift of the 3' splice site of exon 2 (designated by #1 in Figure 6) caused a frame shift, and thus the initiation codon in exon 3 was used. As a result, the N-terminal sequence was shortened by 39 aa compared with the isoform for V1. Furthermore, V2 lacked a 41-aa sequence corresponding to exon 7 by exon skipping. mRNA2 lacked a 5-aa sequence by the 15-bp downstream shift of the 5' splice site of exon 7 (#2). V1 had 5-aa insertion by the 15-bp downstream shift of the 3' splice site of exon 18 (#3). The dbEST contained ESTs carrying not only these four variations but also other variations including the shift of splice site or skipping of exon 4, 6, 10, 11, 12, 15-21, suggesting the presence of diverse AS variants of *GOLGB1*.

GOLGB1 is an integral membrane protein involved in linkage between a Golgi membrane and a COPI vesicle (Sönnichsen et al., 1998). This protein has no N-terminal secretory signal sequence, but has a C-terminal transmembrane domain. Most of the cytoplasmic part is composed of a coiled-coil structure in which the AS variants had deletion or insertion. This structure is thought to be involved in regulation of retrograde trafficking to the endoplasmic reticulum in Golgi apparatus through binding of small GTPase such as Rab6 and Rab1 (Rosing

et al., 2007). Thus, each AS variant may play a role in the regulation of this trafficking. To elucidate the detailed mechanism, further investigation is necessary using these AS variants.

Figure 6. The exon-intron structure of alternative splicing variants for *GOLGB1*. C1 was cloned from the ARPE-19 cDNA library and C2 from the Y79 cDNA library. The relative position of a transcription start site was indicated on exon 1. Arrowheads represent the following sequence variations: #1, the downstream shift of the 3' splice site (28 bp); #2, the downstream shift of the 5' splice site (15bp); #3, the downstream shift of the 5' splice site (15 bp). mRNA1 and mRNA2 correspond to GenBank Accession No. D25542.1 and X75304.1, respectively. Our clones correspond to AB371588.1 and AB593126.1.

3.3.3. Filamin A, Alpha (*FLNA*)

FLNA was most abundantly found in our libraries as a long-sized gene with >7kbp. *FLNA* is an actin-binding protein involved in change in cell shape and migration through crosslinking of actin filaments and linking actin filaments to membrane glycoproteins. ARPE-19 and Y79 libraries contained eight clones (7.3 – 8.2 kbp) and one clone (8.4 kbp), respectively. These clones were classified into four variants as shown in Figure 7. V1 and V2 were main components in ARPE-19 cells. V2 lacked exon 30, resulting in deletion of an 8-aa sequence. V3 lacked exon 38-41 because of AS between the middle splice site in exon 37 and the middle splice site in exon 42. Y79-originated V4 started from a 135-bp upstream TSS compared with V1, resulting in the generation of a novel initiation codon that caused 27-aa extension of the N-terminal sequence.

Figure 7. The exon-intron structure of alternative splicing variants for *FLNA*. Eight clones obtained from ARPE-19 were classified into three variants (V1-V3). V4 was obtained from Y79. The relative position of a transcription start site was indicated on the first exon. "No." represents the number of obtained clones. Arrowheads represent the following sequence variations: #1, the 96-bp upstream shift of the 3' splice site of exon 37; #2, the 72-bp downstream shift of the 5' splicing site of exon 42. RefSeq1 and RefSeq2 correspond to GenBank Accession No. NM_001456.3 and NM_001110556.1, respectively. Our clones correspond to AB191259.1 - AB191260.1, AB371574.1- AB371579.1 and AB593010.1.

GenBank contained 3 mRNAs with a full ORF except for the nine clones we registered. The sequence of mRNA1 (X53416) was constructed by combining seven fragments cloned from a human endothelial cell (Gorlin et al., 1990). mRNA2 (AK090427) originated from a single mRNA and had the same initiation codon as V4, but lacked exon 30. Although this clone seems to be near full-length cDNA, the registrant regarded it as a truncated clone maybe because of no evidence for intactness of the 5' end of the cDNA. mRNA3 (GU727643) was synthesized with RT-PCR based on RefSeq. RefSeq1 corresponding to mRNA1 has exon 1, which uses an upstream alternative promoter. Its ORF starts from the same initiation codon with V4. Our nine clones had no exon 1. There were 14 sequences having exon 1 in dbEST. RefSeq2 was constructed based on our clone V1 except for exon 1. The dbEST contained a sequence (CN421698) that has the same deletion as V3.

FLNA has a rod-like structure composed of 24 repeats of the beta-pleated sheet unit: an actin-filament binding domain (Rod1, repeats 1-15), a partner protein binding domain (Rod2, repeats 16-23), a self-assembly domain (repeat 24), and a hinge linking the domains (Hinge-1 and Hinge-2) (Nakamura et al. 2011). V2 lacked the 8-aa residues that were located in the last repeat 15 of Rod1. V3 lacked the 114-aa sequence that was the part of repeats 18 and 19 of Rod2. Since these repeats are known to bind to several partner proteins, these isoforms may lose a function borne by the corresponding repeat.

3.3.4. *Filamin B, Beta (FLNB)*

FLNB and FLNC as well as FLNA are a member of a filamin family. The ARPE-19 libraries contained four *FLNB* clones (8-9 kbp) and one *FLNC* clone (9156 bp). The *FLNC* clone corresponded to RefSeq (data not shown). All clones for FLNB were different AS variants as shown in Figure 8. Four RefSeqs are constructed based on our four clones. They had a similar TSS. V4 had a total of 47 exons and the other three variants lacked exon 26 (93 bp, 31 aa). V2 lacked 11-aa residues due to the 33-bp upstream shift of 3' splice site of exon 31 (designated by #1 in Figure 8). V1 and V4 had a shorter exon 47 due to the use of an alternative polyadenylation signal. GenBank contained two mRNA sequences except for our clones. These two sequences corresponding to V1 were constructed by combining the sequences of cDNA fragments (Takafuta et al., 1998; Xu et al., 1998). Xu et al. (Xu et al., 1998) have reported near full-length cDNA clone (9.5 kb) for V3 derived from a single mRNA. The dbEST contained four clones possessing a shortened exon 31 found in V2 and two clones possessing exon 26 found in V4.

Figure 8. The exon-intron structure of alternative splicing variants for *FLNB*. Four clones were all different variants. Four RefSeqs are constructed based on our four clones as shown in parenthesis. The relative position of a transcription start site was indicated on the first exon. Arrowhead #1 represents the 33-bp upstream shift of the 3' splice site of exon 31. Our clones correspond to AB191258.1 and AB371580.1- AB371582.1.

FLNB has a domain structure similar to FLNA. V4 encoded an isoform possessing 31-aa insertion in the middle part of repeat 31 due to the insertion of exon 26. The isoform encoded by V3 lacked Hinge-1 of 24-aa residues corresponding to exon 31. V2 encoded an isoform lacking the 11-aa C-terminal half of Hinge-1. The deletion of these aa sequences might affect the function of each isoform through the change of binding ability to the partner proteins as well as FLNA. For example, van der Flier et al. showed that an FLNB fragment lacking a part of repeat 19-20 or C-terminal repeat 24 obtained using RT-PCR had a different binding ability to integrin beta subunit (van der Flier, 2002). Furthermore, they showed that the expression pattern of these variants varied from tissue to tissue and during myogenesis. We have to keep in mind that this kind of experiment using RT-PCR shows the expression level of only a partial sequence of transcript and the expression pattern does not reflect the change of the full-length transcript.

3.3.5. Eyes Shut Homolog (*EYS*)

EYS is an extracellular matrix specifically produced in photoreceptor cells (Abd El-Aziz, 2008; Collin et al., 2008). Recently, we showed that one-third of Japanese patients with retinitis pigmentosa had founder mutations in the *EYS* gene. RefSeq1 for the *EYS* gene comprises 43 exons as shown in Figure 9 and the length of mRNA is 11 kb. In GenBank, there are two short RefSeqs terminating by exon 11. RefSeq2 has a long 3'-UTR. RefSeq3 uses an alternative promoter located between exon 2 and exon 3, resulting in the formation of a new exon 1. The Y79 libraries contained two clones only for short variants. Although V1 was a very-long-sized clone with an insert of 7,898 bp, it terminated by exon 11 containing a long 3'-UTR and encoded the N-terminal 594-aa sequence as well as RefSeq2. The exon 11 of RefSeq2 was split due to splicing. V2 terminated by exon 4 and encoded a short isoform of 318 aa. The *EYS* protein comprises 27 EGF-like domains and 5 laminin G-like domains. Thus, the isoform encoded by V1 terminated at the middle of the sixth EGF-like domain, and the isoform for V2 at the middle of the third EGF-like domain. The function of these short forms of the *EYS* protein remains to be solved.

Figure 9. The exon-intron structure of alternative splicing variants for *EYS*. Two variants were cloned from the Y79 cDNA library. The relative position of a transcription start site was indicated on the first exon. RefSeq1, RefSeq2 and RefSeq3 correspond to GenBank Accession No. NM_001142800.1, NM_001142800.2, and NM_198283.1, respectively. Our clones correspond to AB593114.1 and AB593112.1.

4. FULL-LENGTH cDNA LIBRARIES DERIVED FROM OTHER SPECIES

The power of the vector-capping method was first demonstrated by the transcriptome analysis of budding yeast. Miura et al. performed a large-scale analysis of full-length cDNA libraries prepared from budding yeast cells growing exponentially in a minimal medium and meiotic cells (Miura et al., 2006). They identified 11,575 TSSs associated with 3,638 genes, suggesting that most yeast genes have two or more TSSs. They also identified 45 previously undescribed introns, including those spliced alternatively. Furthermore, they found 667 transcripts in the intergenic region and 367 transcripts derived from antisense strands of known genes. These results suggest that many genes remain unidentified even in an intensively analyzed simple organism such as budding yeast.

Since the vector-capping method was published in 2005 (Kato et al., 2005), it has been adopted by various research projects to construct cDNA libraries from various tissues of various species: plants such as burma mangrove (Miyama et al., 2006), miniature tomato (Aoki et al., 2010), Chinese cabbage (Abe et al., 2011), rubber tree (Suzuki et al., 2012); mammals such as macaque monkey (Osada et al., 2009), pig (Uenishi et al., 2012), common marmoset (Tatsumoto et al., 2013); parasites such as *Haemaphysalis* (Zhou et al., 2006), *Echinococcus* (Watanabe et al., 2007), *Babesia* (Aboge et al., 2008); hagfish (Uchida et al., 2010); *Bombyx mori* nucleopolyhedrovirus (Katsuma et al., 2011). In many cases, it seems to have been difficult to obtain a large amount of starting material. The vector-capping method requires only several micrograms of total RNA. This seems to be one reason why this method was adopted to prepare the libraries from the above samples. The cloning ability of a long-sized cDNA was confirmed by the cloning of very-long-sized genes (9.1kb and 9.8kb) that encode egg case silk from a wasp spider (Zhao et al., 2006).

5. PROBLEMS ON IDENTIFICATION OF AS VARIANTS

5.1. AS Variants of Rare or Long-Sized Genes

In the above sections, I have described some problems in identifying AS variants using the conventional methods. A serious problem occurred in the case of a long-sized gene. The combination of alternative promoter usage, multiple alternative splicing sites, and alternative polyadenylation can produce diverse forms of transcripts. The partial sequence analyses using RT-PCR or RNA-seq do not disclose this combination. To determine the precise structure of the AS variant, it is necessary to determine the full sequence of a single mRNA. One solution for this requirement is to determine the full sequence of a full-length cDNA derived from a single mRNA.

Another problem is related to the intactness of the full-length cDNA. In the case of an abundant gene, many cDNA clones can be obtained. If these cDNAs are shown to start at the similar site by comparing their 5'-end sequences, we could regard them as a full-length or near full-length cDNA having a capped site sequence. However, a rare gene may give only one cDNA clone, thus we cannot judge the intactness of this cDNA. The same problem occurs in the case of very short or very long genes. It may be difficult to judge whether the cDNA are derived from intact mRNA or degraded mRNA. The vector-capping method solves these

problems. We can judge the intactness of the cDNA by inspecting the presence of the additional dG at the 5' end of the cDNA.

5.2. Synthesis of Full-Length cDNA

It has been difficult to obtain a full-length cDNA for a rare or long-sized gene using conventional methods. Here, the problems are shown with regard to each step of cDNA synthesis.

(1) Oligo(dT) Priming

The conventional methods usually use an oligo(dT) primer of ~20 nt to synthesize the first-strand cDNA. When mRNA has a short A stretch, the oligo(dT) primer can accidentally hybridize to this site and be used for cDNA synthesis, resulting in missing the downstream part of mRNA to a poly(A) tail. A good example is an *AIPL1* gene shown in section 3.2.1. We observed several other examples of such mispriming (data not shown). The vector-capping method uses a vector primer possessing approximately 60-nt dT at one end of the vector. The long dT tail may rarely prime a short A stretch in mRNA.

(2) Reaction Conditions

According to our experience, the amount of template mRNA, reverse transcriptase and substrate nucleotides seem to be essential factors that are related to biases by the expression level or size of mRNA. Usually the first-strand cDNA synthesis is carried out using several micrograms of poly(A)⁺RNA. In these reaction conditions, most reverse transcriptase and substrate nucleotides seem to be consumed to synthesize cDNA mainly from abundant or short-sized mRNAs, causing biases by the expression-level and size of mRNA. In the vector-capping method, total RNA is used as a template in place of poly(A)⁺RNA to synthesize the first-strand cDNA under the same reaction conditions. Thus, the amount of enzyme and substrate might be enough to synthesize cDNA from rare or long-sized mRNAs. Omitting mRNA purification steps also may help to reduce these biases.

(3) PCR Step

Some conventional methods including the oligo-capping method contain a PCR step in the procedure for preparing the cDNA library. The amplification step by PCR may cause bias by the expression level and the size of mRNA. In fact, when the full-length cDNA libraries prepared from monkey liver and kidney by the oligo-capping method were compared with those prepared by the vector-capping method, the redundancy of the vector-capped libraries is lower than those of the oligo-capped libraries (Osada et al., 2009). To synthesize rare or long-sized cDNAs, the PCR step should be avoided.

(4) Restriction Enzyme Treatment

The conventional methods contain a linker attachment step, in which a oligonucleotide linker with a restriction enzyme site (e.g., NotI, EcoRI, SalI, XhoI, SfiI et al.) are ligated to the double-stranded cDNA and then after cutting by restriction enzyme the cDNA are introduced into a vector. If the cDNA has the same restriction enzyme site as the linker, it is difficult to

obtain full-length cDNA or any cDNA in some cases. The examples are shown in the above sections on *LHX3* and *NRL*. Many clones registered in dbEST seem to be a truncated cDNA that was generated due to this step.

(5) Size Fractionation

Some protocol contains a size fractionation step to remove short cDNA fragments. This step should be avoided because there are many short transcripts having a poly(A) tail. We observed such short full-length cDNAs with < 100 bp (data not shown).

5.3. Vector-Capping Method

The vector-capping method solves all the above problems. Thus, this will be the most effective method to synthesize genuine full-length cDNAs at present. However, this has one limitation. It is difficult to obtain full-length cDNA clones from a low-quality RNA sample containing highly degraded mRNA, because this protocol does not contain a step for experimentally selecting full-length cDNAs, such as a cap-dependent linker ligation in the oligo-capping method. In addition, it requires a lot of labor and cost to search novel AS variants from the vector-capped libraries. This is the case particularly when the target cell expresses genes with low complexity. In that case, we should use a subtraction or normalization protocol together. If the target gene has been decided, we may isolate in advance target cDNA using a probe for the target gene.

CONCLUSION

Here I have demonstrated that the vector-capping method provides us with a high-quality cDNA library composed of genuine full-length cDNA clones derived from a single mRNA and that the obtained clones can be used to effectively identify AS variants. This library contains many full-length cDNA clones for rare or long-sized genes whose intactness is guaranteed. By analyzing these clones, we can identify novel AS variants for rare or long-sized genes that have been difficult to obtain using conventional methods. These results suggest that comprehensive, in-depth analysis of full-length cDNA clones isolated from the vector-capped libraries is the most effective way to identify an entire set of AS variants. Furthermore, these full-length cDNA clones can be used as a resource for producing the encoded proteins. I hope that the vector-capping method will be widely used for analyzing full-length AS variants derived from various tissues of various species.

Chapter 23

AN EPIGENETIC VIEW ON ALTERNATIVE SPLICING

ABSTRACT

Genome-wide analysis indicate that alternative splicing of mRNA precursors (pre-mRNAs) affects the vast majority of human genes. Alternative splicing provides a fundamental mechanism to increase transcriptome complexity, allowing the production of two or more mRNA variants that often encode proteins with different, sometimes opposite functions. Its importance is underscored by the observation that misregulated alternative splicing can lead to human diseases. Pre-mRNA splicing has long been known to be regulated by *cis*-acting sequence elements and *trans*-acting protein factors. In higher eukaryotes, it mostly occurs co-transcriptionally so that it is not surprising that a role for chromatin and epigenetic factors in the regulation of exon inclusion is now emerging. In this review, we will discuss the most recent findings on the roles played by chromatin structure on the modulation of the cotranscriptional splicing reactions. In particular, we will focus our attention on how the modulation of the transcribing RNA polymerase II, the changes in nucleosome architecture and the presence of different histone modifications contribute to the regulation of the splicing process.

1. INTRODUCTION

Most eukaryotic mRNAs are generated from their primary transcripts (pre-mRNAs) through capping at the 5' end, removal of introns by splicing and 3' end cleavage and polyadenylation. These processes can lead to transcript diversification through the phenomenon of alternative splicing (AS). AS can lead to the specific inclusion or the skipping of exons (or

even parts of an exon), to the selection of different 3' terminal exons, or to intron retention. It is likely that more than 95% of all human genes give rise to alternative mRNAs (Pan et al., 2008; Barash et al., 2010). The effect of AS in expanding the protein repertoire might partially underlie the apparent discrepancy between gene number and the complexity of higher eukaryotes. Given the crucial role of AS in the regulation of gene expression, it is not surprising that alterations in this process are associated with cancer and neurodegenerative pathologies, such as spinal muscular atrophy (SMA) and amyotrophic lateral sclerosis (ALS) (for review, David et al., 2010, Cooper et al., 2009).

RNA splicing occurs in the spliceosome, a large complex composed of five small ribonucleoprotein particles (U1, U2, U4/U6 and U5 snRNPs) and many non-snRNPs splicing factors. SR proteins and hnRNP proteins were the first non-snRNPs splicing factors identified. These proteins are components of the basal splicing machinery but, since their concentration can influence splice site selection, they contribute to AS. In addition, a growing list of tissue-specific AS regulators have been identified in recent years (for review see Wahl et al., 2009).

The mature 3' ends of mRNAs, with the exception of replication-dependent histones transcripts, are generated by endonucleolytic cleavage of the pre-mRNA followed by polyadenylation of the upstream cleavage product. Pre-mRNA 3'-end processing requires also several *trans*-acting protein factors (for review see Proudfoot, 2011). A large proportion of mammalian genes also undergoes alternative polyadenylation generating mRNA variants that differ in their coding sequence and/or in their 3' untranslated regions (UTRs), thereby potentially regulating the stability, localization and translation efficiency (for review see Tian et al., 2013)

Although the general mechanisms of pre-mRNA splicing and 3'-end processing have been well studied, how specific exons are chosen and are included in the mature transcript is still not completely clear. Both the splicing machinery and the 3' end processing complex assemble on conserved sequence elements that define the intron-exon junctions, the so-called splice sites (ss), the branch point sequence (BPS), a poorly conserved sequence located near the 3' end of the intron, and the polyadenylation site (PAs, Figure 1). In addition to these core signals, splicing is influenced by other regulatory elements (Wang et al., 2008). These elements are conventionally classified as exonic splicing enhancers (ESEs) or silencers (ESSs) depending whether they function to promote or inhibit inclusion of the exon they reside in, and as intronic splicing enhancers (ISEs) or silencers (ISSs) if they enhance or inhibit usage of adjacent splice sites or exons from an intronic location. These regulatory elements function by recruiting *trans*-acting factors that activate or inhibit splice site recognition and/or spliceosome assembly.

The early steps of spliceosome assembly, which provide the main targets for regulation, involve recognition of the consensus splice sites at both ends of the intron. Members of the SR family of splicing factors play essential roles in the early steps of splice-site recognition. These proteins contain one or two N-terminal RNA recognition motifs (RRMs) that function in sequence-specific RNA binding and a C-terminal domain rich in alternating arginine and serine residues, referred to as RS domain that is required for protein-protein interactions with other RS domains. SR proteins bound to specific RNA sequence elements are thought to recruit key splicing factors enhancing the recognition of splice sites and influencing splice site selection in a concentration-dependent manner (for review, see Zhou et al., 2013). This raises the possibility that tissue-specific expression of SR proteins may drive variation in splicing patterns. In addition, members of the family of hnRNP have also been shown to participate in the regulation of AS. Often these proteins have an antagonistic function to SR proteins. So far, only a few

systems of regulated splice site choice have been genetically or biochemically dissected and most regulatory proteins and sequence elements have not yet been identified.

Figure 1. Schematic structure of an eukaryotic pre-mRNA. The pre-mRNA contains different *cis*-acting regulatory elements. The intron sequences are highly variable except for a conserved short region at 5' and 3' ends, called splice sites (ss), and the branch point sequence (BPS) within the intron. Exons and introns also contain splicing enhancers (ESEs and ISE) or silencers (ESSs and ISSs). At the 3' end of the pre-mRNA signals are found that direct cleavage and polyadenylation. The canonical polyadenylation signal consists of a conserved hexameric sequence, termed polyadenylation site (PAS) that precedes the CA dinucleotide where cleavage of the pre-mRNA occurs (cleavage site, CS). The CS is followed by a U- or UG- rich stretch of nucleotides (downstream element, DE).

This review concentrates on recent advances in the study of the cross-talk between chromatin structure and AS regulation. First, it focuses on several recent reports, that found large-scale evidence for a connection between nucleosome positioning and exon-intron architecture. An interesting emerging concept from these studies is that nucleosome positioning may reflect the exon-intron architecture. Then, we review histone modifications that may contribute to splicing regulation. Finally, intragenic DNA methylation and evidence for a role of methylated cytosine (5-mC) in exon definition are reviewed.

2. ALTERNATIVE SPLICING AND RNA POL II ELONGATION RATE

Although initially splicing and 3' end formation have been studied *in vitro* as independent processing events, biochemical, cytological and functional evidence suggest that all the events leading to the synthesis of the mature mRNA are coupled to transcription (for review see Kornblihtt et al., 2013). Several RNA processing factors are recruited on the C-terminal domain of RNA polymerase II (RNA Pol II) and are deposited on the nascent pre-mRNA molecule during transcription elongation. Transcription-coupled AS can be explained by the differential recruitment of AS factors on the transcribing polymerase. The carboxy-terminal domain (CTD) of the largest RNA Pol II subunit has a key role in the coupling of transcription with the different maturation steps that are required for the biogenesis of the mature mRNA molecule. The CTD undergoes extensive phosphorylation on Ser2 and Ser5 of the heptapeptides repeats (YSPTSPS). These phosphorylation events are associated to the transition from initiation to elongation. It has been proposed that RNA Pol II pausing at promoter proximal sites is phosphorylated on Ser5 but not on Ser2 (de la Mata et al., 2003; Morris et al., 2005). Several AS factors, including SR proteins bind to the phosphorylated CTD (Das et al., 2007).

Recently, a novel mode of splicing factor recruitment by Argonaute proteins has been uncovered (Ameyar-Zazoua et al., 2012). Argonaute proteins are the catalytic components of the cytoplasmic RNA-inducing silencing (RISC) complex responsible for RNAi silencing. In

the nucleus, they regulate transcription by inducing gene silencing. Interestingly, silencing of AGO1 and AGO2 was found to influence AS of the CD44 gene. Moreover, both AGO proteins physically interact with components of the splicing machinery, suggesting that they may participate in the recruitment of the splicing machinery to chromatin.

Figure 2. Kinetic coupling between transcription elongation and alternative splicing. Alternative exons are generally characterized by weak splice sites. The inclusion of an alternative exon with a weak 3'ss near a constitutive exon can be modulated by the elongation rate of RNA Pol II. A fast, processive polymerase, which is associated with a CTD phosphorylated in Serine 2 (pSer2), favors the skipping of the alternative exon. In contrast, phosphorylation of Serine 5 (pSer5) is associated with a slow processive Pol II that favor the inclusion of the alternative exon allowing more time for splice site recognition.

Another way to explain the coordination of splicing with transcription is a kinetic coupling between AS and transcription elongation (for review see Srebrow et al., 2006; Allemand et al., 2008, Figure 2). Slowing down the polymerase may favor the use of weak splice sites by delaying the synthesis of downstream splice sites, thus facilitating the recognition of suboptimal exons. The observation that inhibitors of histone deacetylation favors skipping of alternative exons (Nogués et al., 2002), possibly by promoting hyperacetylation of core histones thus facilitating transcription elongation, points towards an involvement of chromatin structure in the elongation-dependent regulation of AS. Further support to this idea has been recently provided by the report that the catalytic subunit Brahma (BRM, *SMARCA2*) of the chromatin remodelling complex SWI/SNF modulates AS by affecting RNA Pol II elongation rate (Batsché et al., 2006, see below). Recently, the kinetic coupling of alternative splicing and RNA Pol II elongation was shown to be influenced by DNA damage (Muñoz et al., 2009). These authors found that UV irradiation inhibits transcription elongation by inducing the hyperphosphorylation of RNA Pol II carboxy-terminal domain. This in turn can influence AS decisions, influencing the choice between cell survival and cell death.

3. NUCLEOSOMES AND ALTERNATIVE SPLICING

Nucleosomes are the basic building blocks of chromatin and consist of 147 base pairs of duplex DNA wrapped around a protein multi-subunit complex called “histone octamer”, which in turn is composed of two copies of each of the four canonical histones proteins H2A, H2B, H3 and H4. The positively charged residues of the histone proteins contact the phosphate backbone of the DNA every 10,4 base pairs, so that the 147 bases stretches of the DNA wrapped around the histone octamer make nearly 14 contacts (Khorasanizadeh, 2004).

During transcription, nucleosomes represent a “roadblock” to gene expression, as their presence may affect the accessibility to the DNA and prevent the polymerase from reading the template strand. Chromatin remodeling complexes are able to overcome these problems, as they displace the nucleosomes starting from the promoter region of a given gene, so that complete transcriptional activation can occur. During elongation, nucleosomes are evicted or remodeled in front of the transcribing polymerase, and are subsequently replaced in the region behind the polymerase (Workman, 2009). The replacement of nucleosomes after the passage of the RNA Pol II is an important step that allows nucleosomes exchange and/or recycling (Kulaeva et al., 2007).

Since 75-90% of genomic DNA is wrapped around nucleosomes (Wu et al., 2009), nucleosome occupancy certainly contributes to the regulation of gene expression. In fact, nucleosomes follow a non-random distribution in the genome, as they mainly cover the coding regions. In contrast, non-coding regions are characterized by a low nucleosome occupancy. These “open” regions are preferentially located at transcription start sites (TSS), which may be depleted of nucleosomes to retain their accessibility for transcription factors binding (Segal et al., 2006; Liu et al., 2011). The differential nucleosome occupancy observed at the level of coding versus non-coding regions possibly depends on specific genomic sequences. As a matter of facts, it has been proposed that coding regions are enriched in nucleosomes because of their relatively high GC content, while non-coding regions, that are characterized by a low GC content, are depleted of nucleosomes (Schwartz et al., 2009). These observations allow the computational prediction of nucleosome binding sites on the genomic sequence, that can be subsequently validated experimentally (Segal et al., 2006; Wu et al., 2009; Liu et al., 2011).

The first evidence of a connection between AS and nucleosome organization dates back to 1991, when Beckmann and colleagues observed that the distance between consecutive 5' and 3' splice sites in the pre-mRNA is very similar to the unit of DNA wrapped around a single nucleosome (Beckmann et al., 1991). Thanks to technological advancements in high-throughput screenings, this initial observation was supported by robust experimental evidence. Schwartz and colleagues found a consistently higher nucleosome occupancy on exons with respect to flanking introns, possibly due to the higher GC-content found in coding regions (Schwartz et al., 2009). Moreover, well-positioned nucleosomes were found in exons with weak splice signals and in isolated exons, suggesting that nucleosomes may facilitate the recognition of these exons. A difference in the levels of nucleosome occupancy was also found between constitutive and alternatively spliced exons. The same observations were independently published by Tilgner and colleagues (Tilgner et al., 2009), who found that a high nucleosome occupancy in genomic regions containing exons with weak splice sites. Moreover, they found a striking connection between nucleosome positioning and exon definition. By analyzing high-throughput data from human and from *C.elegans*, these authors found that high nucleosome

occupancy on specific exons is evolutionarily conserved and correlates with the exon inclusion rate. More specifically, exons which are constitutively included in the mature transcript have high nucleosome occupancy within and upstream of their sequence. Those nucleosomes, that are located within the exons, are preferentially localized at the centre of the coding sequence, and not at the level of the splice sites. Tilgner and colleagues finally propose that the nucleosome-dependent exon definition is independent from transcription, as non-expressed genes, as well as actively expressed genes, show a comparable nucleosome occupancy in their exons. The consideration that nucleosomes define the exons independently from transcription is sustained by the study of Andersson and coauthors (Andersson et al., 2009). In this report, the authors reasoned that the presence of nucleosomes in inactive genes suggests that they participate in the exon-intron architecture of the genome in completely opposite way compared to their role in the regulation of transcription. As a matter of fact, they found significant difference in nucleosome occupancy at the level of actively expressed genes versus silenced genes. In particular, they found that low-expressed genes display a relative depletion of nucleosomes around their TSS, while actively transcribed genes show a peculiar nucleosome pattern that defines the region around their TSS. Nucleosomes located around the TSS are highly mobile and prone to be displaced, in accordance with their role in transcription regulation. In contrast, nucleosomes located in the body of the gene are more resistant to displacement (Weiner et al., 2010).

For what the position occupied by nucleosomes respect to the 5' and 3' splice sites is concerned, the debate is still open, as observations differ. Some reports (see for example Kogan et al., 2005) indicate that nucleosome patterns are evolutionarily conserved and that they mirror the distribution of the splice sites. In this scenario, nucleosomes would participate to the splicing reaction by "covering" and protecting the splice sites from possible mutations. Instead, other reports (see for example Andersson et al., 2009; Tilgner et al., 2009) found a specific enrichment of nucleosomes within the exons, and not at the level of the 5' and 3' splice sites. Despite these differences, there is a general consensus that nucleosomes are recruited on the specific genomic regions based on their sequences.

The correlation between nucleosome positioning and AS has been very recently addressed by Keren-Shaul and colleagues (Keren-Shaul et al., 2013). Based on the evidence that loss of RNA Pol II causes a relaxation of chromatin (Weiner et al., 2010), and that transcription causes massive rearrangements in nucleosomes positioning (Kulaeva et al., 2007), the authors investigated whether the AS reaction could also participate in regulating chromatin structure. They found that overexpression of mutated forms of the U1 snRNA, either with low or strong efficiency in binding to the 5' splice sites present in the pre-mRNA, has an impact on chromatin structure. Specifically, a more efficient binding of U1 snRNA induces an increase in exon inclusion and a concomitant increase in nucleosome occupancy at the level of internal alternative exons. This is paralleled by a local increase in the amount of pausing RNA Pol II at the level of the alternative exon, a feature which is linked to exon inclusion (de la Mata et al., 2003). Even if the mechanism underlying the AS-dependent increase in nucleosome occupancy is still unclear, it appears to be independent from transcription, as both the low-efficient and the strong-efficient form of U1 have the same effects in terms of RNA Pol II recruitment.

But how nucleosomes positioning influences the cotranscriptional AS reaction? The mechanism remains elusive, but some possible explanations have been proposed. First, nucleosomes may affect the RNA Pol II processivity, which in turn may have an impact on exon inclusion (Keren-Shaul et al., 2013). This putative connection may be true, even if several

reports agree that nucleosome positioning on exons is independent from transcription (Tilgner et al., 2009; Keren-Shaul et al., 2013). Second, nucleosomes may influence AS thanks to post-translational modifications (PTMs) present in the tails of the histones that constitute them. The growing body of evidence connecting histone PTMs and AS suggests that this explanation is highly probable, and it is sustained by the observation that the nucleosomes that define the exons in the genome are not only positioned in a predictable way but they also carry specific histone PTMs (Andersson et al., 2009, see below). Third, nucleosomes, either directly or indirectly, may recruit the splicing factors on the splice sites of the nascent pre-mRNA. Even if the splicing reaction can occur *in vitro* without the presence of nucleosomes, the same reaction is more efficient *in vivo* when it is coupled to transcription (Das et al., 2006). This consideration, together with the robust evidence that nucleosomes are positioned more stably on alternative exons with weak splice sites (Tilgner et al., 2009), indicates that nucleosomes are a crucial player in defining the exon-intron architecture in the genome.

4. CHROMATIN REMODELING AND ALTERNATIVE SPLICING

Eukaryotic cells have evolved a number of enzymatic complexes that are able to change the chromatin architecture. These protein complexes, known as chromatin remodelers, are divided in four main families: SWI/SNF, ISWI, CHD and INO80. These families share common features, such as the ability to disrupt the contacts between nucleosomes and DNA, their multi-subunit composition, and the presence of a constitutive and evolutionarily conserved ATPase subunit (Clapier et al., 2009). The ATP-driven chromatin remodelling activity of these complexes regulates the accessibility of the different regions of the chromosome (Hargreaves et al., 2011). The “remodelers” play crucial roles in regulating DNA replication, repair, and recombination, as well as gene expression. In particular, chromatin remodelers are involved in the regulation of transcription, by controlling the accessibility of transcription factors (TFs) at the level of the promoters and by facilitating transcription elongation in the body of the gene. Chromatin remodelling complexes are recruited to specific sites of the chromatin thanks to presence, in their subunits, of protein domains (bromodomains and chromodomains) that recognize specific histone modifications (such as acetylation, methylation and phosphorylation) (Clapier et al., 2009).

As reported by a paper from Muchardt’s lab (Batsché et al., 2006), it has been proposed that chromatin remodelling complexes play also a role in the AS regulation. Specifically, the authors report that Brahma (BRM), one of the two mutually exclusive ATPase subunits of the human SWI/SNF chromatin remodelling complex, is able to modulate the AS reaction by enhancing the inclusion of alternative exons which reside in the body of the genes. In particular, when BRM is present inside the SWI/SNF complex, it interacts with components of the splicing machinery such as U1 and U5 snRNPs. BRM is also able to cooperate with Sam68, a well-known exon inclusion enhancer. This interaction, as well as the shared interaction between Brm, Sam68 and U5, increases the inclusion of alternative exons. Concomitant with the presence of this complex, accumulation of RNA Pol II-pSer5 was observed in the same genomic regions. The pSer5 modification of the CTD is linked to a slow processive form of the polymerase and to exon inclusion (de la Mata et al., 2003). Most importantly, the positive effect played by BRM on exon inclusion seems to be specifically connected to exons with weak splice

sites, which, without a molecular mechanism able to increase their inclusion, would be instead excluded from the mature transcript. In conclusion, this paper suggests a intriguing link between chromatin remodelling complexes and cotranscriptional AS. The observation that BRM plays a role in the exon inclusion process is substantially confirmed by an independent paper, in which Ito and colleagues (Ito et al., 2008) reported that Brm is involved in the inclusion of *TERT* exon 7, by an interaction with p54^{nrb}. Interestingly, modulation of exon 7 inclusion may have an impact on the activity of the telomerase, the protein which is encoded by the *TERT* gene,

Interestingly silencing of different subunits of the SWI/SNF complex in *Drosophila* cells indicate that this complex is not only involved in the AS of internal exons, but also in the choice of different polyadenylation sites. A first report provides evidence that the *Drosophila* SWI/SNF complex is associated with the nascent pre-mRNPs (Tyagi et al., 2009). A more recent paper from the same group then demonstrated that selective knock-out of the *Drosophila* core SWI/SNF subunits (Brm, Snr1 and Mor) affects the alternative processing of a subset of transcripts, changing the relative abundance of the isoforms produced (Waldholm et al., 2011).

5. HISTONE POST-TRANSLATIONAL MODIFICATIONS AND ALTERNATIVE SPLICING

All the four major histone types that are included in the nucleosome have an amino-terminal region that protrudes beyond the nucleosome surface. This “tail” is the target of a wide variety of post-translation modifications (PTMs). In contrast to the DNA methylation, the only chemical modification that occurs on DNA so far identified, histones have at least 100 different PTMs, which include methylation, acetylation, phosphorylation and ubiquitination (Bernstein et al., 2007). Table 1 summarizes the major PTMs affecting transcription and splicing.

From a mechanistic point of view, histones PTMs have an impact on the stability of the interaction between nucleosomes and DNA, modulate the protein-protein interactions involving histones, and/or generate the platform that triggers other subsequential histone PTMs. Acetylation of the histone tails, catalyzed by histone acetylases (HATs), removes the positive charges present on the lysine residues, thereby decreasing the interactions between the tails and the negatively charged phosphate groups present in the DNA. As a consequence of HATs activity, chromatin structure becomes more relaxed and transcription is generally facilitated. On the contrary, de-acetylation of the histone tails, catalyzed by the histone deacetylases (HDACs), results in a more closed and compacted chromatin structure associated with transcriptional silencing. Compared to acetylation, methylation, the second major histone PTM, has a different effect as the addition of a methyl group does not alter the relative charge of lysine and/or arginine residues. For this reason, methylation (catalyzed by histone methylases, HMTs) and demethylation (catalyzed by histone demethylases, HDMs) of histone tails have different outcomes on chromatin compaction depending on their target residue and on the presence of other methyl or acetyl groups in close proximity (Zentner et al., 2013).

The advent of epigenetic studies focused on genome-wide mapping of histone PTMs, has allowed to correlate the presence of these modifications to different gene expression outcomes. It has now become clear that the combination of the modifications targeting the histone tails residing in a specific genomic region creates an “histone code” that can be read by

evolutionarily conserved chromatin-interacting proteins, that contain specific interaction domains. For example, the methylation mark is known to recruit proteins containing the chromodomain module (Eissenberg, 2012) while histone acetylation can be read by proteins containing bromodomains (Filippakopoulos et al., 2012). These protein-protein interactions are strictly regulated by “histone writers” (such as the already mentioned HATs/HDACs and HMTs/HDMs) that modulate both the relative abundance of a specific modification in a given genomic region and the amount of PTMs targeting a single residue.

Compared to acetylation, the patterns of methylation are even more complex, because a single lysine can harbor one (me1), two (me2) or three (me3) methyl groups, and the relative level of methylation of a single lysine may also lead to completely opposite effects. For example, it has been proposed that mono-methylation of lysine 9 of histone 3 (H3K9me1) recruits proteins that facilitate transcription (Barski et al., 2007), while di- (H3K9me2) and tri-methylation (H3K9me3) of the same residue are associated to transcriptional silencing (Barski et al., 2007, Rosenfeld et al., 2009). Specific methylases are dedicated to the task of adding the methyl group to a lysine which already harbors one modifications, while other enzymes are able to add this PTM if two methyl groups are already present, thus enhancing the complexity of the regulation of this process. Moreover, whole-genome mapping of histones modifications has revealed that different histone PTMs map in different regions of the body of a gene and are linked to specific outcomes. Some modifications, like H3K4me3 are enriched at the level of transcription start sites (Kolasinska-zwierz et al., 2009), whereas others, such as H3K36me3 and H3K79me3, are instead present in the body of the gene (Spies et al., 2009); moreover, marks such as H3K27me2, have been mapped at the level of intergenic heterochromatin regions (Kolasinska-zwierz et al., 2009). Table 1 is an attempt to simplify the great complexity of the histone codes that has so far been identified, highlighting their proposed functions.

Regarding the connections between histone’s PTMs and co-transcriptional AS, it has been observed that not only specific histone marks, such as H2BK5me1, H3K27me3 (Andersson et al., 2009) and H3K36me3 (Spies et al., 2009), are enriched in the gene body and at the level of the exons, but that different modifications also lead to diverse splicing outcomes. For example, it has been proposed that H3K36me3, one of the most studied and debated histone modification, is enriched at the level of the genomic regions containing exons, which are constitutively included in the mature transcript, while it is generally less present at the level of alternative exons (Kolasinska-zwierz et al., 2009).

How can the presence of specific histone marks influence the pattern of AS? Two mechanisms have been proposed so far. First, similarly to transcription regulation, histone modifications can provide a platform for the recruitment of specific splicing regulators. For example, it has been shown that H3K36me3 recruits proteins which are able to modulate the splicing outcomes, such as MRG15 (and adaptor protein), PTB (a splicing factor which interacts with MRG15) and SRSF1 (a SR protein which enhances exon inclusion) (Pradeepa et al., 2003). Second, histone modifications can influence RNA Pol II processivity. For example, Schor and colleagues demonstrated that depolarization of neurons decreases the inclusion of the murine *Ncam* exon 18 via local changes in specific histone PTMs which in turn influence the Pol II elongation rate (Schor et al., 2009). Specifically, an increase in the acetylation of H3K9 (either triggered by depolarization or by Trichostatin A, TSA) in the genomic region surrounding the variable *Ncam* exon 18 causes an increase in the chromatin accessibility, which locally allows to the polymerase to proceed faster, resulting in exon skipping.

Interestingly, this hyperacetylation is paralleled by the increase in the H3K36me3 mark in the all the actively transcribed *Ncam* gene region, indicating a more general change in the chromatin landscape and a possible crosstalk between the histone PTMs. A more recent report by Chen and colleagues demonstrated that the H3K27me2 mark induces an increase in the

elongation rate of the polymerase (Chen et al., 2012). This is possible because H3K27me3 recruits the JMJD3 and KIAA1718 demethylases on a subset of genes. These genes are marked at their promoter-proximal regions with the H3K27me3 and H3K4me3 marks, and are also associated with a promoter-proximal, paused RNA Pol II. The JMJD3/ KIAA1718 complex demethylates the H3K27me3 mark, and this event releases the Pol II, triggering the productive elongation phase. This is possible because the JMJD3 complex recruits elongation factors, such as SPT6, SPT16, CDC73, and SETD2. The silencing of JMJD3 and of KIAA1718 reduces the Pol II elongation rate in the bodies of the monitored genes, a feature previously linked to exon inclusion (de la Mata et al., 2003; Batsché et al., 2006). Interestingly, the H3K27me3 mark has been mapped in the bodies of transcribed genes (Schwartz et al., 2006), suggesting that it may play a role in regulating the intragenic RNA Pol II processivity.

6. INTRAGENIC DNA METHYLATION AND ALTERNATIVE SPLICING

DNA methylation consists in the addition of a methyl group to the C5 position of the cytosine in a cytosine-phosphate-guanine (CpG) dinucleotide by a DNA-methyltransferase enzyme of the *Dnmt* family (Hattori et al., 2004). In vertebrate genomes the frequency of CpG dinucleotides is lower than expected based on random chance. This is due to the intrinsic instability of the methyl-cytosine that can spontaneously deaminate to thymine. For this reason, CpGs are evolutionarily lost over time, resulting in a progressive general depletion of this dinucleotide (Bird et al., 1980). The CpGs display a completely non-uniform distribution along several genomes, and this dinucleotide appears restricted to clusters termed “CpG islands” (CGIs). CGIs are defined as stretches of interspersed DNA sequences, both enriched in cytosine/guanine content and in the presence of several CpG dinucleotides. CGIs are usually 200 base pairs long, display a lower CpG depletion compared to other genome regions, and harbor unmethylated cytosines (Ponger et al., 2002). These clusters of CpG dinucleotides tend to localize in the genomic regions near to the transcription start sites (TSS) of the majority of housekeeping and/or ubiquitously expressed genes, where they constitute a key element defining eukaryotic promoter regions (Gardiner-Garden et al., 1987). A recent report (Vavouri et al., 2010) indicates that CpG-containing promoters have a peculiar transcription-associated chromatin organization, which can be depicted as an ordered and conserved distribution of nucleosomes containing specific histone marks.

CGIs are important elements that epigenetically regulate the expression of eukaryotic genes during differentiation and development. Genome-wide studies revealed that unmethylated CGIs are prominent in undifferentiated cells and in the embryo, and that this methylation-free state is associated with active transcription. During differentiation, some CpG dinucleotides contained in the CGIs acquire the methylation mark in a tissue and cell-specific fashion. This methylated state is associated with silencing of the downstream genes, as the methyl-cytosine directly inhibits the binding of transcription factors and recruits epigenetic modifiers, such as HDACs and Polycomb (PcG) proteins, which are associated with a long-term gene silencing (Deaton et al., 2011).

An enrichment of the CpG dinucleotide has also been detected in intragenic regions and their evolutionary conservation suggests that these sequences hold the potential to epigenetically regulate other “layers” of gene expression, such as AS. It has been observed that the content of

the CpG dinucleotide is significantly higher in the introns localized upstream to alternative cassette exons compared to introns preceding constitutive exons or localized downstream to alternative cassette exons. In particular, the CpG frequency is higher in the region flanking the acceptor site of the alternative cassette exons, and is not linked to the relative intron length and/or to the presence of *Alus* sequences (Malousi et al., 2008). An intriguing correlation between the peculiar localization of the CpG dinucleotide at the level of internal cassette exons and the regulation of AS is provided by data published in 2005 by Zoghbi's group (Young et al., 2005). The paper provides evidences that methyl-CpG-binding protein 2 (MeCP2), the protein containing mutations linked to the emergence of the Rett syndrome, is involved in the regulation AS. MeCP2 was previously described to specifically bind the DNA at the level of methylated CpGs (Nan et al., 2001). By protein co-immunoprecipitation assays, Young and collaborators discovered that MeCP2 directly interacts with the Y box-binding protein 1 (YB-1), a protein which mediates the DNA-RNA interactions involved in the regulation of transcription, translation (Khono et al., 2003) and AS (Stickeler et al., 2001). The MeCP2/YB-1 interaction is RNA-dependent, but independent from methylated DNA. This observation suggests that YB-1 is a RNA-dependent MeCP2 binding protein and that the interaction specifically occurs during transcription and it is separated from the previously reported roles of YB-1 in DNA repair and replication. By using splicing reporter minigenes, the authors demonstrated that the MeCP2/YB-1 complex directly modulates the inclusion of internal alternative exons. This observation was then confirmed by a splicing-sensitive, genome-wide survey of the AS events of endogenous genes expressed in the cerebral cortex of the MeCP2 model mice. Interestingly, this mouse model of Rett syndrome exhibits AS alterations relative to the inclusion of cassette exons containing the YB-1-binding ACE domain, such as the genes encoding the NR1 subunit of the NMDA receptor and the *Dlx5* gene. While this paper demonstrated that MeCP2 can contribute to AS regulation, it did not explore the correlation between cytosines methylation and MeCP2-engagement at the level of intragenic CpGs. However, a very recent report established a link between intragenic CpG methylation and regulation of AS. Khare and collaborators (Khare et al., 2013) focused their attention on 5-hydroxymethylcytosine (5-hmC), a derivative of methylated cytosine (5-mC), which is highly abundant in human and mouse brain tissues. Using assays able to discriminate between 5-hmC and 5-mC, the authors detected a striking brain-specific enrichment of 5-hmC in genomic regions containing genes involved in synaptic functions. In this specific class of genes, 5-hmC marks the exonic side of the exon-intron boundaries in a brain-specific fashion and has a direct effect on the splicing outcomes. In facts, the authors found that an increase in the 5-hmC content in the region proximal to the exon and/or within the exon is prominent in constitutively included exons, while the 5-hmC modification is less abundant in exons which are subjected to AS.

From the mechanistic point of view, it has been proposed that the presence of intragenic CpG methylation inhibits the binding of proteins involved in AS regulation and/or induces the formation of peculiar chromatin structures. Shukla and collaborators (Shukla et al., 2011) focused their attention on the *CD45* gene, which is a widely used model gene to study the regulation of AS. During lymphocyte differentiation the regulated inclusion/skipping of *CD45* variable exon V5 gives rise to protein isoforms that can be easily monitored. As most alternative exons, exon V5 has weak splice sites, so that it is usually skipped. The authors reported that the genomic region surrounding exon V5 displays an accumulation of the CCCTC-binding factor (CTCF), a protein that has been described for its roles in insulating inactive genomic regions and promoting long-range interactions between distant genomic regions. The accumulation of

CTCF on the variant V5 exon promotes its inclusion in the nascent transcript by inducing a localized pausing in the RNA Pol II. An inverse correlation between CTCF accumulation and methylation of the cytosines present in exon V5 was instead observed, indicating that methylcytosine inhibit CTCF binding. The DNA methylation patterns change during lymphocyte differentiation, and this dynamic methylation at the level of intragenic sites provide an astonishing mechanistic correlation between exon V5 inclusion and the differentiation process.

Undifferentiated cells

Differentiated cells

Figure 3. Epigenetic regulation of CpG islands (CGIs) during eukaryotic differentiation and development. Alternative splicing can be modulated during differentiation in a methylation-dependent manner. In undifferentiated cells when intragenic CpG are unmethylated, a MeCP2/YB-1 complex is able to directly modulate inclusion of the alternative exons of CD44, and of CT/CGRP (Young et al., 2005). In differentiated cells, instead a preferential skipping of the alternative exon is observed due to an increase of 5-hydroxymethylcytosine (5-hmC) in the proximal region of constitutive exons, and of methylated intragenic CpGs.

To extend this observation, the authors took advantage of CTCF ChIP-seq data, that showed that the great majority of the binding sites for this protein reside in intragenic regions. Other reports, basing on sequencing data, focused their attention on the correlation between intragenic cytosine methylation and the formation of peculiar chromatin structures (see for example Chodavarapu et al. 2011). Figure 3 is a schematic representation of the current knowledge regarding the intragenic methylation-dependent regulation of AS.

CONCLUSION

It is well-established that chromatin structure plays an important role in the transcriptional control of eukaryotic gene expression, but only recently it has become clear that chromatin organization can also contribute to AS regulation. AS participate in critical biological processes including cell growth and differentiation, cell death, pluripotency, development (Cooper et al., 2009; Kalsotra et al., 2011). The importance of AS is underscored by the fact that 95% of human genes produce alternatively spliced transcripts (Pan et al., 2008; Wang et al., 2008). However, the functional impact of the vast majority of AS events has not been characterized in any way, nor the molecular mechanisms underlying the selection of specific alternative exons are fully understood. These remain major challenges for future research. Moreover, a greater understanding of the structure-to-function relationship – that is, how chromatin organization can influence specific splicing events and what is the biological function of the different mRNA variants – will be required. In this respect, recent studies have revealed a novel layer of complexity. Although this review focuses on the cross-talk between chromatin proteins and splicing factors, it should be mentioned that the emerging class of long non-coding RNAs (lncRNAs) was shown to contribute to epigenetic regulation of gene expression. lncRNA can guide the organization of higher-order ribonucleoprotein complexes thereby modulating the activity of chromatin-modifying complexes (for review Mercer et al., 2013). No doubt that future work will likely uncover new, unexpected mechanisms that connect lncRNAs and chromatin states to regulate AS.

Chapter 24

ALTERNATIVE RNA SPLICING AND REGULATION OF NITRIC OXIDE SIGNALING

Iraida G. Sharina*

Department of Internal Medicine, Division of Cardiology,
University of Texas Medical School, Houston, TX, US

ABSTRACT

Alternative splicing expands transcriptome diversity and allows cells to meet the requirements of an ever-changing extracellular environment. It has been more than 30 years since nitric oxide (NO), a gaseous free radical, was recognized as a critical physiologic signaling molecule. Since then the list of known NO-directed functions has grown substantially to include regulation of smooth muscle function in vascular and gastrointestinal systems, inhibition of platelet aggregation and adhesion, neurotransmission and neuromodulation, regulation of cellular respiration and cytotoxicity, mitochondrial biogenesis and, immune defense. However, the importance of alternative splicing in regulation of enzymatic components of NO signaling pathway started to emerge only recently. Our understanding of the mechanisms governing this process remains very limited and awaits systematic investigation. In this chapter we will attempt to summarize the available information on alternative splicing of major enzymes mediating canonical NO transduction through the secondary messenger cGMP. We will highlight evidence accumulated from different laboratories that suggest splicing of enzymes in the NO/cGMP pathway, including nitric oxide synthases, heterodimeric soluble guanylylcyclase and cGMP-dependent protein kinase, is very complex and strongly affects NO signaling in response to various environmental cues. Future studies will certainly bring new, exciting insights into the role that alternative splicing plays in NO/cGMP biology.

Keywords: nitric oxide, soluble guanylylcyclase, splicing, regulation

INTRODUCTION

Pre-mRNA splicing is one of the major modes of regulation of gene expression in metazoan organisms. Alternative pre-mRNA processing may generate numerous transcripts from a single protein-coding gene; thus largely increasing the information content and complexity of the genome. Recent studies indicate that more than 80% of human genes undergo alternative splicing [1, 2]. It is estimated that close to 75% of alternative exons introduce changes in the resulting protein products. Similar to transcription, splicing can be regulated both on a global level and in a gene-specific manner by a wide number of cell signaling mechanisms [2, 3]. Alternative splicing enables cells to tailor the expressed proteome in response to environmental stresses and to meet physiological requirements of different tissues. The importance of this process is underlined by a number of human diseases associated with alterations in splicing and splicing regulation [4, 5].

In this review we focus on the role of alternative splicing in regulation of the Nitric Oxide (NO) signaling pathway. We also summarize available information on splicing of major enzymes participating in NO/cGMP signal transduction.

NO/cGMP PATHWAY AND ITS ROLE IN PHYSIOLOGY

It has been more than 30 years since the gaseous free radical nitric oxide was recognized as a critical physiologic signaling molecule.

Biological functions of NO are mediated through several types of molecular interactions, which are traditionally divided into two groups: (1) direct effects of NO, such as reactions with hemoproteins, thiols and superoxide, and (2) indirect effects mediated by an increase in intracellular cyclic GMP level (Figure 1). In this chapter we will focus our attention on the second type, “classical” NO signal transduction mediated by cGMP. The primary source of enzymatic production of NO is via the family of Nitric Oxide Synthases (NOS), which includes endothelial (eNOS), neuronal (nNOS) and inducible (iNOS) isoforms. High output iNOS is expressed primarily in circulating phagocytic cells of immune defense. iNOS is constitutively active and produces high concentrations of NO that functions as a non-specific cytotoxic agent

in anti-microbial and anti-parasitic defense [6]. NO produced by iNOS is not mediated by cGMP, and prolonged activation of iNOS in systemic inflammation results in a precipitous drop of blood pressure in septic shock.

Transient increase in intracellular concentrations of Ca^{2+} is an important regulatory feature in regulation of eNOS and nNOS activity. These enzymes were originally identified in endothelial and neuronal tissues where they produce low concentration fluxes of NO needed to initiate the NO/cGMP signaling cascade. Additional processes, e.g., phosphorylation of eNOS by Akt signaling kinase [7], may modulate their ability to generate NO. Generated NO binds to the heme moiety of soluble guanylyl cyclase (sGC) and activates the enzyme to form the secondary messenger cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP). sGC is the only NO-sensitive guanylylcyclase and represents a unique receptor for this gaseous transmitter. Increased intracellular cGMP concentrations regulate the activity of several cGMP-dependent effectors, including cGMP-binding protein kinases, cGMP-dependent phosphodiesterases, and cyclic nucleotide gated ion channels [8].

Activation of protein kinase G (PKG I α, β) plays a central role in active relaxation of smooth muscle in vascular and gastric tissues. PKG reduces muscle contractile tone through several mechanisms. PKG facilitates Ca^{2+} extrusion to extracellular space and the reuptake of Ca^{2+} to sarcoplasmic reticulum cisterns by activation of Ca^{2+} /ATPase pumps. It also prevents Ca^{2+} influx by inhibiting the activation of Big Potassium Ca^{2+} -activated channels (BK_{Ca}).

Figure 1. Molecular mechanisms of nitric oxide signaling via cGMP. NO and Citrulline (Cit) are synthesized from L-Arginine (L-Arg) by NO synthases (eNOS, nNOS) located in neuronal, endothelial or other cells. NO synthases are activated by Calmodulin in complex with Ca^{2+} . Produced NO traverses cell membranes and binds and activates soluble guanylylcyclase (sGC). cGMP produced by sGC binds and activates cGMP-dependent protein kinase (PKG), cyclic nucleotide gated ion channels (CNGC) and cGMP phosphodiesterases (PDEs). PKG phosphorylates and activates Ca^{2+} ATPase pumps in sarcoplasmic reticulum (SR) and plasma membrane, and big potassium channels (BK_{Ca}) in plasma membrane. These processes initiate and amplify NO/cGMP signal transduction.

In addition, PKG facilitates dephosphorylation of myosin light chains via stimulation of myosin light chain phosphatase activity, thus directly inducing relaxation of smooth muscle cells (SMC) [9].

cGMP-regulated phosphodiesterases (PDEs) are another important group of cGMP-effector proteins. PDEs play an important role in determining the actual levels of intracellular cyclic nucleotides in virtually all type of tissues by catalyzing the breakdown of intracellular levels of cGMP and cAMP[9].

Cyclic-nucleotide gated channels (CNG) are directly activated by cGMP and constitute a special class of downstream cGMP effectors. Upon cGMP binding, CNG channels nonselectively allow the passage of divalent cations through plasma membrane which mediates sensory functions such as olfaction and photo-reception [10].

Since the discovery of the NO/cGMP signaling pathway the list of known physiological functions mediated by it has grown substantially. The eNOS-sGC axis plays a crucial role in cardiovascular homeostasis. NO is an important endogenous vasodilator that regulates blood vessel tone through activation of sGC. NO/cGMP signaling prevents thrombosis by inhibiting platelet aggregation and leukocytes adhesion, thereby increasing blood fluidity [11, 12]. In addition, NO participates in vascular remodeling through inhibition of vascular SMC proliferation and neointima formation in vascular injury [13]. Therefore, impairment of NO/cGMP signaling is regarded as a hallmark of endothelial dysfunction and contributes to the development of a vast majority of cardiovascular disorders including coronary artery disease, atherosclerosis and hypertension [14]. Activation of the NO/cGMP pathway results in relaxation of smooth muscle of corpus cavernosum resulting in penile erection. Clinical introduction of PDE5 inhibitors, most notably Viagra (sildenafil), which potently and selectively inhibits cGMP hydrolysis, was a landmark for the treatment of male erectile dysfunction [15].

The NO/cGMP pathway promotes angiogenesis by activating proliferation and migration of endothelial cells [16]. It also participates in cellular metabolism by acutely stimulating uptake and oxidation of glucose and fatty acids; inhibiting synthesis of glucose, glycogen and fat in skeletal muscle; and enhancing lipolysis in white adipocytes [17]. In addition, NO/cGMP signaling regulates the permeability of tight junctions facilitating transit across gut and blood-brain barrier and maintaining the homeostasis of the microenvironment in the seminiferous epithelium during spermatogenesis [18].

Neuronal NOS is the isoform responsible for non-adrenergic, non-cholinergic (NANC) inhibitory neurotransmission in the gut. nNOS and sGC deficient animal models exhibit strong gastrointestinal phenotype characterized by severe or fatal gastrointestinal obstruction [19, 20]. Dysfunctional nNOS enzyme has been implicated in several diseases of the GI tract, including oesophageal achalasia, pyloric stenosis, and colonic dysfunction [21].

The canonical NO/cGMP pathway modulates long-term changes of synaptic activity in numerous brain regions. It contributes to distinct forms of learning and memory, such as fear conditioning, motor adaptation, and object recognition. cGMP generated upon NO activation of sGC promotes presynaptic transmitter release through regulation of Ca^{2+} signaling and cytoskeletal rearrangements. In the postsynaptic junction, cGMP modulates trafficking and subunit composition of α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors. Phosphorylation of glutamate receptor 1 (GluR1) by PKG increases its surface expression in hippocampal pyramidal cells, while in cerebellar Purkinje cells PKG induces endocytotic removal of AMPARs from postsynaptic membranes. Dysfunction of

NO/cGMP signaling is implicated in the development of neurodegenerative and psychiatric diseases including Morbus, Alzheimer's and schizophrenia [22].

NO/cGMP signaling mediates nociceptive processing of pain signals in the superficial dorsal horn of spinal cord, and is an important contributor to sensitization during inflammatory and neuropathic pain. Selective inhibition of this pathway in spinal cord holds promise for the development of new powerful analgesics [23].

A detailed description of all the functions of the NO/cGMP pathway is out of the scope of this chapter. There is a multitude of excellent scientific reviews on this subject, some of which were referenced above. Here, we have tried to draw the attention of the reader to the notion that NO signaling via cGMP is highly ubiquitous in metazoan physiology and is undeniably important in human health and disease. Preliminary insights indicate that regulation of NO/cGMP pathway is rather complex and occurs at all levels, including transcription, post-transcriptional regulation, translation and protein modification [24-27]. In this chapter we will attempt to summarize the available data regarding splicing of the enzymes which represent the core molecular machinery of the NO signal transduction. We will try to underline the fascinating complexity of NO/cGMP regulation, most of which still awaits discovery and characterization.

NEURONAL NITRIC OXIDE SYNTHASE (nNOS)

Neuronal NOS was the first NO synthase to be purified and cloned from brain tissue. It is most abundantly expressed in central and peripheral nervous tissue, and plays a central role in neurotransmission and neuromodulation [28]. Its gene locus encompasses more than 200 kb and has highly complex structural organization. nNOS splice forms are generated through alternative splicing by exon insertions/deletions and involve usage of multiple promoters [29]. Four nNOS protein isoforms (five including canonical, full size nNOS- α) encoded by multiple splice form transcripts possess different regulatory and catalytic properties [30]. The nNOS- α and nNOS- μ variants contain the postsynaptic density-95/discs large/zone occludens-1 homology (PDZ) domain. PDZ domain allows enzyme to associate with cell membranes, thereby facilitating its activation by calcium fluxes [31]. In addition to defining intracellular localization, the PDZ domain plays an important role in regulating the activity of nNOS isoforms by mediating protein-protein interactions with protein inhibitor of NOS (PIN) [32], the NMDA receptor [33], syntrophin [31], and carboxyl terminal PDZ ligand of NOS (CAPON) [34]. nNOS- α "canonical" protein has highest catalytic activity and is encoded by multiple splice transcripts with alternative UTR regions. nNOS- μ contains a unique 34 aa insertion and possess similar enzymatic properties as nNOS- α isoform. It is predominantly expressed in myocardium and skeletal muscle in rats, and in rat and human penis and urethra [35]. nNOS- β and nNOS- γ isoforms lack the PDZ domain and are localized primarily in the cytoplasm. While catalytic activity of nNOS- β is comparable to the activity of nNOS- α , the activity of nNOS- γ is significantly impaired and represents no more than 3% of nNOS- α 's activity [31]. nNOS- β isoform was demonstrated to mediate penile erection [36]. An additional splice variant called nNOS-2 with a 105 aa deletion was identified in mouse brain and human neuroblastoma cell lines [37, 38].

Precise biological functions of individual nNOS isoforms remain unclear. Expression profiling indicates that some of them participate in the development of various pathologies. For example, nNOS- γ and nNOS- β are upregulated in amyotrophic lateral sclerosis and might play a role in mediating oxidative damage in neuronal tissue [39]. Also, the expression of nNOS- γ splice form was detected in atherosclerotic plaques of apoE knock-out mice, and was suggested to play a role in plaque formation [40]. One of the alternative nNOS- α transcripts is regulated by a hypoxia-inducible promoter, which confers the ability to rapidly upregulate nNOS expression in response to hypoxia [41]. Selective downregulation of nNOS- α and nNOS-2 transcripts indicates that these splice variants may play pharmacologically different roles in modulation of morphine analgesia [42]. Thus, nNOS alternative splicing seems to be subject to diverse expressional regulation and plays a crucial role in modulating nNOS function and activity.

ENDOTHELIAL NITRIC OXIDE SYNTHASE (eNOS)

eNOS is a key regulator of vascular homeostasis and its activity is strongly implicated in maintenance of a healthy vascular phenotype. Until very recently no information was available about alternative splicing of the eNOS gene. However, the dry spell was broken by a very interesting report demonstrating that the human eNOS gene does undergo alternative splicing in intron 13, which results in the expression of three eNOS splice transcripts designated eNOS13A, B and C [43]. Recombinant expression and functional analysis indicate that eNOS13A protein heterodimerizes with canonical eNOS monomer which results in reduction of eNOS activity. Therefore, it might play the role of a dominant negative mutant. Expression of all three eNOS splice variants has been detected in human endothelial cells and in most examined human tissues. High levels of eNOS13A isoform expression was detected in human testis. Additionally, presented results indicate that alternative splicing of eNOS exon 13 is regulated by adjacent A/C-rich intronic splicer-enhancer elements, providing a unique glimpse into the mechanism of this regulation [43]. In a follow up report, the mechanism of eNOS alternative splicing was dissected further, demonstrating that DNA topoisomerase I is directly involved in this process [44]. Inhibition of DNA topo I activity by siRNA treatment abolished the TNF- α -induced increase in expression of inhibitory eNOS splice forms, and prevented the decline of NO biosynthesis in human endothelial cells. This data suggested that alternative splicing of eNOS might be an additional mechanism modulating the rate of NO production in an early response to inflammatory signaling.

NO-INDUCIBLE HETERODIMERIC SOLUBLE GUANYLYL CYCLASE (sGC)

sGC is a heme-containing obligatory heterodimer composed of α and β subunits [45]. Its expression has been detected in all studied tissues, albeit at varying levels and with different subunit compositions [46]. Although sGC was originally purified from cytosolic fraction, it was subsequently found associated with cellular membranes in a variety of cell types [47-53]. Each sGC subunit has two isoforms $\alpha 1/\alpha 2$ and $\beta 1/\beta 2$, encoded by a total of 4 separate genes.

Only sGC heterodimers containing the $\beta 1$ subunit have been shown to possess catalytic activity in vivo [54]. While α subunits ($\alpha 1$ and $\alpha 2$) have similar catalytic properties, they differ in their tissue and subcellular distribution [46, 51, 54]. Several studies have demonstrated that transcripts derived from all sGC genes undergo alternative splicing [55-60].

The $\alpha 1$ sGC gene is found to be expressed in all examined tissues with the highest levels detected in vasculature. To date, $\alpha 1$ splice variants are the most diverse and best characterized group [27]. The variety of human $\alpha 1$ transcripts is consolidated into seven transcript types encoding four different protein isoforms which are named A, B, C and D (NCBI, www.ncbi.nlm.nih.gov). All $\alpha 1$ splice form transcripts can be sub-divided into two groups based on the encoded protein isoforms. The first group includes transcripts 1 to 4, which encode an identical 690 aa protein, isoform A (canonical $\alpha 1$ sGC). These transcripts differ from each other only in their 5'- and 3'-UTR sequences, which are likely to play roles in regulating mRNA stability. The second group includes transcripts 5 to 7 which encode unique polypeptides named isoforms B, C and D. All three $\alpha 1$ sGC protein splice forms have been biochemically characterized and shown to generate heterodimers with $\beta 1$ sGC subunit resulting in diverse functional properties [60, 61]. The N1- $\alpha 1$ variant, Transcript 6, isoform C, encodes $\alpha 1$ sGC protein with extensive deletion in the catalytic domain. It displays properties of a dominant negative mutant and inhibits the activity of the $\alpha 1/\beta 1$ sGC heterodimer. In contrast, the C- $\alpha 1$ sGC splice form, Transcript 5, isoform B, encodes a fully functional protein despite a 240 aa deletion of the N-terminal regulatory domain. sGC heterodimers containing C- $\alpha 1$ sGC are much less sensitive to protein degradation induced by sGC heme oxidizing agent ODQ. C- $\alpha 1$ sGC also partially protects the level of $\beta 1$ sGC, when co-expressed in BE2 cells [60]. The C- $\alpha 1$ sGC splice form is expressed at high levels during differentiation of human embryonic stem cells (hES) [59]. Intracellular distribution of C- $\alpha 1$ isoform varies from canonical $\alpha 1$ sGC [59], and is localized to the more oxidized environment of endoplasmic reticulum [61]. The relative amount of C- $\alpha 1$ transcript was increased by exposure to H_2O_2 in several human cell lines constitutively expressing $\alpha 1/\beta 1$ sGC [62]. The $\alpha 1$ isoform D (Transcript 7) generates a sGC heterodimer with drastically impeded activation by NO and NO-independent sGC activators. Interestingly, our recent studies demonstrate increased non-functional $\alpha 1$ sGC splice forms, $\alpha 1$ -IsoC and IsoD, and decreased functional oxidation-resistant C- $\alpha 1$, $\alpha 1$ -IsoB, variant expression in diseased aortic tissue collected from patients undergoing aortic repair surgery (Sharina *et al*, submitted). These results suggest that $\alpha 1$ sGC splicing likely plays an important role in regulation of sGC activity, and could be one of the mechanisms contributing to impaired NO/cGMP signaling in vascular disease.

The $\alpha 2$ sGC transcripts have more restricted patterns of expression and are highly abundant in neuronal tissues [46]. The $\alpha 2i$ splice variant demonstrates properties of a dominant negative mutant when co-expressed with canonical subunits [55]. Recently, the existence of a splice variant homologous to the human $\alpha 2i$ has been detected in rat pituitary and liver tissues [57]. In that report, semi-quantitative RT-PCR demonstrated that $\alpha 2i$, but not $\alpha 2$ sGC transcript, is upregulated in response to estrogen in adult rat pituitary gland. This interesting observation suggests that the splicing of the $\alpha 2$ sGC subunit might be regulated by sex hormones in rodents.

The ubiquitously expressed $\beta 1$ sGC is indispensable for sGC activity [19, 46, 63]. Heterogeneity of $\beta 1$ sGC transcripts was first demonstrated by Chhajlani *et al.* who showed the presence of two mRNA species in human lung tissue [58]. In addition to the canonical transcript, they observed a shorter mRNA (NCBI GenBank Accession AF020340,) predicted to encode a non-functional peptide containing 33 aa deletion in the proximity of a catalytic

domain. Presently several $\beta 1$ sGC splice form transcripts exist in the GeneBank database. Their detailed description can be found in the review [27]. Sequence analysis indicates that a number of unique $\beta 1$ polypeptides with multiple N- and C-terminal deletions and insertions are encoded by these splice transcripts. No functional characterization of $\beta 1$ sGC splice forms has been performed so far. Changes in protein sequence of the $\beta 1$ sGC encoded by these splice variants are likely to affect the regulatory properties of sGC heterodimers that would include them. Human $\beta 1$ sGC splice forms have been isolated from a variety of different tissues including lung, fetal brain, placenta, and tongue tumor, suggesting complex tissue specific splicing of the $\beta 1$ sGC gene.

To date, the biological role of the $\beta 2$ sGC subunit gene remains a mystery [55, 64]. The coding region for the $\beta 2$ subunit lacks the methionine codon, and the expression of $\beta 2$ protein has yet to be detected *in vivo*. According to several publications, the recombinant $\alpha 1/\beta 2$ heterodimer possesses very low, if any, enzymatic activity and was suggested to act as a dominant negative isoform to other subunits [65, 66]. It is the only known sGC subunit which is reported to possess activity as a homodimer [67]; this resembles particulate guanylyl cyclases. Similar to other sGC subunits, the $\beta 2$ pre-mRNA undergoes alternative splicing. Several $\beta 2$ splice variants have been described in the literature. Two alternative transcripts encode the N-terminally truncated splice isoforms corresponding to the splice variants originally described by Behrends' group (Acc. Ns CR615161 and AK296746). The β_{2SV} sGC, which is generated by the skipping of exons encoding the N-terminal heme-binding domain of the protein, was isolated from human corpus cavernosum [68]. Based on deletion size and location, it was suggested that sGC enzymes containing this β_{2SV} splice form should be NO-insensitive. Another splice form encoding an N-terminally truncated $\beta 2$ sGC protein was isolated from human gastric carcinoma [56]. In a recent report, a new splice variant encoding an ORF with additional amino acids at the N-terminus was described [69]. Interestingly, the same report demonstrated that the 5'UTRs of the two alternative $\beta 2$ sGC transcripts ('canonical' and new splice form) possess an active internal ribosome entry site (IRES). Moreover, the activity of the 5'UTR from the alternative transcript was much higher than that of the 'canonical' one, supporting the concept that alternative splicing plays a role in modulation of $\beta 2$ sGC expression.

cGMP-DEPENDENT PROTEIN KINASE G (PKG I)

The biological importance of PKG in transducing NO signaling was first appreciated in the promotion of vascular smooth muscle relaxation and inhibition of platelet aggregation. Numerous advances in methodology and generation of PKG deficient mice extended the roles of PKGI to regulation of gastrointestinal motility, endothelial permeability, erectile function, cardiac protection, and modulation of proliferation of SMC [9]. Two PKG enzymes (PKGI and PKGII) are encoded by two separate genes in mammals. We will focus on PKGI since it is the main cGMP-dependent kinase which transduces the NO signal. There are two well described splice variants of PKGI, designated as PKGI α and PKGI β . These splice proteins differ by a unique stretch of 100 amino acids in the N-terminal regulatory domains which share only 36% homology. This difference exerts a profound influence on PKGI α and PKGI β cGMP binding affinity, selectivity of enzymes to cyclic nucleotides analogs, specificity towards protein

substrates, subcellular localization, and state of activation [9]. The leucine zipper encoded in the N-terminal regulatory domain appears to be responsible for selective protein–protein interactions of PKGI isoforms. For example, only PKGI α , but not PKGI β , associates with antidepressant-sensitive serotonin transporter (SERT) to modulate serotonin uptake [70]. Interaction with the leucine zippers of PKGI α dimers with myosin light chain phosphatase (MLCP) is required for MLCP phosphorylation and activation [71]. The leucine zipper of PKGI α mediates binding and activation of Regulator of G-protein Signaling-2 (RGS2), facilitating vascular smooth muscle cell relaxation [72]. One α -helix located in the leucine zipper of PKGI β mediates specific binding and phosphorylation of two protein substrates, transcription factor II-I (TFII-I) and IP₃ receptor-associated PKG substrate (IRAG) [73]. Association with these proteins also determines PKGI β intracellular localization.

PKGI α binds cGMP with almost 10 fold greater affinity than PKGI β , which probably reflects different physiological roles for these isoforms [74]. It has been proposed that increased expression of PKGI β , with its lower affinity for cGMP, is responsible for the blunted vasodilation response to NO signaling in an angiotensin-hypertensive rat model [75].

Both PKGI isoforms function as homodimers and are found in cytosolic and membrane fractions, segregating into specific cellular compartments in particular cell types. PKGI β is the predominant isoform in platelets, where it is found almost entirely in membrane-bound form; PKGI α is the major isoform expressed in pulmonary vasculature [76]. PKGI α has been reported to protect neuronal cells from apoptosis by phosphorylation of Bad, an apoptosis-regulating BCL-2 family member [77]. One of the most intriguing features of PKGI α is its ability to be activated by oxidative stress, such as exposure to H₂O₂, which induces inter-subunit disulfide bonds and alters enzyme affinity for substrates [78]. Smooth muscle cells expressing redox-insensitive enzyme demonstrated no detectable phosphorylation of myosin light chain (MLC), suggesting that this mechanism plays an important role in regulation of PKGI α function.

cGMP PHOSPHODIESTERASES (PDEs)

PDE's hydrolyze the cyclic phosphate ring in cGMP and cAMP molecules. The products of this reaction, 5'-GMP or 5'-AMP, are inactive as second messengers in cyclic nucleotide-dependent signaling pathways. Therefore, PDEs serve as feedback regulators and terminators of NO/cGMP signaling, and play a crucial role in determining the intracellular cGMP levels. The expression and hydrolytic activities of PDEs, found virtually in all cell types and in almost all subcellular compartments, are subject to complex and dynamic regulatory processes. Mammalian PDEs are represented by 11 families of enzymes derived from 21 genes. Of them, 8 (PDE1 to 3, PDE5 and 6, and PDE9 to 11) are cGMP-hydrolyzing [9]. All PDE genes undergo alternative splicing, generating more than 50 protein isoforms with mostly unknown biological roles. PDEs have highly homologous catalytic domains, but differ in their diverse regulatory N-terminal and extreme C-terminal regions, which function as modulators of activity and protein-protein interactions. Three PDE families, PDE 5, 6, and 9 have 100-fold higher substrate affinities towards cGMP over cAMP and are considered cGMP-specific PDEs [79]. Here we focus our attention on cGMP-specific members of the PDE family. Information on other PDEs can be found in an excellent review by Bender and Beavo [80].

PDE5 is best known as the molecular target for several very successful drugs used to treat erectile dysfunction, such as Sildenafil (Viagra). The protein structure of canonical PDE5 is characterized by the presence of two high affinity binding sites for cGMP in its N-terminal regulatory domain named GAF-A and GFF-B. Three splice variants of PDE5, PDE5A1 to 3, all with alterations in N-terminal domain encoded by alternative first exons, have been identified so far. Transcription of PDE5A2 occurs from an alternative promoter and is regulated by cAMP and cGMP via AP2 and SP1 elements [81]. PDE5 isoforms also demonstrate differential tissue-specific expression. PDE5A1 and A2 splice forms have been detected in multiple tissues while PDE5A3 seems to be restricted only to vascular smooth muscle [82].

PDE6 family members are expressed in the photoreceptor outer segments of mammalian retina, where they play a critical role in the conversion of light signals into photo responses. No functional splice variants for PDE6 genes have been identified so far. However, exon 14 skipping in PDE6B gene was found to be responsible for the drastic decrease in PDE6B protein expression in an atypical retinal degeneration 3 (*atrd3*) mouse model of recessive retinitis pigmentosa [83]. This report draws attention to the importance of faithful mRNA splicing and the deleterious effects of its malfunction in genetic diseases.

PDE9 has the highest affinity for cGMP and is found co-localized with sGC and nNOS in the brain, strongly indicating that it participates in regulation of NO signaling in neuronal tissue [84]. The PDE9A gene locus maps to the region involved in several neurologic diseases including bi-polar disorder [85]. A PDE9 inhibitor is presently under pre-clinical investigation as a possible treatment for Alzheimer's disease [86]. PDE9A pre-mRNA undergoes extremely complex alternative splicing with at least 20 different splice forms identified so far [87]. All variants are alternatively spliced to produce unique changes in their N-terminal protein sequence. Only PDE9A1 and PDE9A5 protein isoforms have been characterized so far. Both isoforms have a high affinity for cGMP, similar K_m values, and 2 fold differences in V_{max} values. They also demonstrate different subcellular localization: PDE9A1 is found preferentially in the nucleus, while PDE9A5 is found in cytosol [88]. The biological roles of other PDE9A splice forms remain to be determined.

CYCLIC NUCLEOTIDE GATED ION CHANNELS (CNGCs)

cGMP produced by NO-activated sGC may directly activate CNG channels. CNG channels are nonselective cation channels; they do not discriminate between alkali ions and allow the passage of divalent ions, including Ca^{2+} . Activation of CNG channels causes membrane depolarization and facilitates excitation of neurons [89]. CNGCs serve as molecular sensors responding to changes in intracellular cGMP concentrations in visual and olfactory systems. In addition, they are found to play roles in neurotransduction and neuromodulation in other brain regions such as hippocampus, the striatum, the hypothalamus, and the locus coeruleus.

CNGCs function as heterotetrameric complexes consisting of two or three different types of subunits. The CNG family is loosely divided into two types of subunits, called A and B subunits. When expressed alone in heterologous systems, A subunits form functional channels, whereas B subunits have been shown to function only as activity modulators of homomeric α subunit channels. They are encoded by six different genes, four for A subunits (A1 to A4) and two for B subunits (B1 and B3). Multiple splice variants have been identified for the CNGA3

and the CNGB1 subunits from various tissues and organisms [90]. Splice forms of A3 gene encode protein isoforms with different N-terminal domains. However, as with many other examples in the NO/cGMP signaling pathway, specific functional roles of splice isoforms remain unexplored. Two splice variants are known for CNGB1, B1a and B1b. These splice variants differ in the glutamic acid-rich part of their N-terminal domains. These domains are responsible for protein-protein interaction and demonstrate tissue-specific expression in rods, photoreceptors, and within the olfactory system [91]. The expression of B1 splice forms was also detected in testis where they demonstrate different localization and sensitivity to cyclic nucleotides. It has been suggested that they play a part in controlling the flagella bending waves in sperm [92].

CONCLUSION

The last 20 years of research in splicing regulation of NO/cGMP signaling has progressed from virtually non-existent to a fast developing and very complex field. Data from multiple laboratories strongly indicate that splicing of NO/cGMP pathway enzymes is a convoluted process modulated by multiple environmental and cellular factors. Emerging evidence suggest that this regulation is crucially important to support NO signaling in normal and pathological conditions.

The diversity of the expressed transcripts allows for a dynamic spatio-temporal regulation of the NO/cGMP pathway in response to multiple physiological signals. Most of the enzymes in NO/cGMP signaling, including NOS, sGC, PKG, CNGs and PDEs, function as multimers, and are often composed of two types of different subunits. Incorporation of splice isoforms into functional multimers creates the potential to generate a great number of unique hetero- and homo-dimers with diverse enzymatic and regulatory properties. The assortment of available alternatively spliced transcripts or splice protein variants may tailor the properties of the enzyme(s) in the pathway to better suit the molecular environment of the cell. This consideration alone is a compelling argument for the importance of alternative splicing in functional regulation of the NO/cGMP pathway.

Alternative splicing fundamentally contributes to NO/cGMP enzyme expression not only by giving rise to alternative protein isoforms, but also by producing transcripts with different regulatory sequences in non-translated regions. These new sequences may affect the stability and translocation of mRNA, as well as its translation. Alternative mRNA transcripts that differ in their 3' and/or 5' UTR regions are likely to play a critical role in regulating mRNA steady-state levels through mechanisms of RNA stabilization and/or inhibitory RNA targeting.

Studies of the regulation of NO/cGMP enzymes through alternative splicing still remain in initial stages of development. Currently the components of splicing machinery involved in the regulation of sGC splicing remain almost completely unknown. Recently our group gained insight into the regulatory mechanism of H₂O₂ induction of the expression of oxidation resistant C- α 1 sGC splice form [62]. Our studies show that H₂O₂ exposure selectively decreases the expression of PTBP1 and hnRNP A2/B1 splicing factors. The same factors were identified by *in silico* analysis as potential regulators controlling the splicing of C- α 1 sGC. Another interesting discovery was made regarding the crucial role of DNA topoisomerase I in regulation of eNOS alternative splicing in response to TNF- α (see eNOS section above, [44]). However,

no systematic investigation of splicing regulation of NO/cGMP enzymes has been done so far. Increasing numbers of reports demonstrate that alternative splicing of different enzymes in the pathway may be altered by similar regulatory factors under inflammatory and oxidative conditions [39-41, 44, 62, 75, 93]. A coordinated regulation of splicing of different enzymatic components of NO/cGMP signaling would facilitate cellular adaptation to oxidative stress and/or the development of diverse pathologies associated with it. In the future, a major challenge will be to define the mechanisms and splicing regulators participating in such coordinated regulation.

Although the biological roles for the majority of splice variants of NO/cGMP enzymes are poorly understood, unraveling them will likely be essential to our understanding of nitric oxide biology. Advances in the understanding of the molecular mechanisms will facilitate the development of new therapeutic strategies allowing targeted manipulation of the pathway through the regulation of splicing of selected components.

ABSTRACT

Genes could produce multiple protein-coding transcripts by alternative splicing (AS). It was known that AS is related to several diseases in generating biological and functional diversity. So, analysis of the mRNA diversity of genes would be important for understanding gene function. Previously, we obtained 1.46 million human full-length cDNAs (FLJ cDNA) and sequenced their 5'-ends. We selected approximately 55 thousand cDNAs from FLJ cDNA and sequenced completely. Our FLJ cDNAs were constructed by an optimized oligo-capping method. Thus, by using 5'-EST data, a lot of valuable information was obtained regarding the diversity of the transcription start site (TSS) and amino acid sequences at the N-terminal ends of proteins. We found that alternative TSSs were utilized for tissue-specific expression. Using this data, we constructed FLJ Human cDNA Database ver. 3.2, <http://flj.lifesciencedb.jp>. But, a lot of AS-related information still remains to be extracted from our 1.4 million cDNA resources. From a huge number of human sequence information, we selected only the reliable cDNAs for the analysis of the mRNA diversity. And, we developed probes which can analyze the mRNA diversity. As a result, by comparing our constructed 5,784 pairs of independent probes, we are able to detect the expression profiles of splicing patterns in 3,413 genes. Moreover, using these probes, we analyzed the mRNA diversity of genes after inducing neuronal differentiation in human NT2 teratocarcinoma cells using all-trans retinoic acid (RA). Analyses of NT2 cells identified 452 RA-responsive genes. The mRNA diversity analysis revealed that the

rate of genes that showed AS in their N-terminus, internal region, C-terminus, is almost the same, respectively.

INTRODUCTION

We think that it is important to understand the variety of mRNA expressed from each gene for the gene functional analysis. Therefore we pay attention to it and analyze this. Because the human gene number was estimated to be only approximately 20,000 genes [1], it was thought that expressing different proteins from one gene frequently caused various life phenomena in humans. As for this variety, many genes change a splice pattern, and it is said that it is realized by alternative splicing (AS) producing multiple mature mRNA by one immature mRNA [2]. AS is a system where different kinds of proteins are often expressed from one gene. It is said that the gene expression program at this RNA stage is controlled for time space in the living organisms, and it is important for creating the complicated various forms and functions in those by this controlled program [3-8]. It is known that it is related to various diseases and that the proteins, where the biological property and function are different, are produced from one gene by AS [9]. When abnormality occurs in AS, which should be originally exact, an abnormal protein, which lacked in a function, and/or a cytotoxic abnormal protein, is produced and may be related to the disease onset [10-11]. Therefore at first it is necessary to analyze the variety of mRNA by each gene to study the influence that the change of the gene expression level gives to a gene function. However, there are many points that must be solved about the variety of the mRNA, including the function of every produced protein-coding transcript, by analyzing and identifying the various mRNA produced by one gene, the mRNA change from one gene by the environment factor and/or the controlling mechanism of producing the variety of mRNA transcribed from one gene.

Therefore first we must question what type of protein-coding transcript was produced by AS from one gene, so we identified various mRNA produced by a gene. Then, we decided to examine the influence that variety of mRNA gave to a gene function by AS to elucidate an unknown gene function and the gene expression control system.

IDENTIFICATION OF TRANSCRIPTION PRODUCTS PRODUCED BY VARIETY OF THE HUMAN mRNA

We thought that identification of various mRNA produced by one gene was important to the gene functional analysis. All human genome sequencing was determined by the human genome-sequencing project [1], but all gene regions transcribed to mRNAs, which encoded proteins, were not necessarily identified. Furthermore, the number of the mRNA, which can theoretically be produced by AS, is enormous because the gene is often comprised of plural exons and the combination is complicated. Therefore, it is very difficult to predict it only from the genome DNA sequence information by *in silico*. It is necessary to analyze sequences of a great number of mRNAs, possibly brought about *in vivo* by AS, and to identify them to elucidate a question of what type of protein-coding transcript is produced by AS of one gene.

Therefore we acquired approximately 1,460,000 of human full length cDNA (FLJ cDNA) from the CAP site of mRNA, which were constructed from approximately 100 kinds of human tissues and cells by the oligo-capping method, and analyzed all 5'-EST (expressed sequence tag), with average sequence lengths of approximately 500 bases [12-14]. We selected approximately 55,000 of FLJ cDNA, which acquired the information for the 5'-EST sequences, and performed full length sequencing [12-15]. Then we built a data set of human cDNA sequences, which included the FLJ cDNA, and performed mapping and clustering with the human genome sequence. The human genome sequence used 18 UCSC hg NCBI Build 36.1. Approximately 55,000 full length sequenced FLJ cDNA sequences and approximately 1,460,000 5'-EST sequences of FLJ cDNAs were used for analysis. We also used approximately 52,000 sequences of the human full length sequenced cDNAs registered with a public database (DB) at the same time, approximately 30,000 sequences of human RefSeq (NCBI Reference Sequences; <http://www.ncbi.nlm.nih.gov/RefSeq/>), approximately 48,000 sequences of human Ensembl sequence (Ensembl, human gene transcripts; <http://www.ensembl.org/index.html>) for analysis. Furthermore, we used the human EST sequence information registered with the public DB and analyzed it. As a result, we built the FLJ Human cDNA Database, <http://flj.lifesciencedb.jp> [15].

Using all sequences mapped to the same chromosomal region, we selected only reliable full length cDNA sequences for a protein coding gene prediction. Using the full-length cDNA selected above, we evaluated each genome locus with a manual for every chromosomal region one by one, whether it was an encoded protein or not. As a result, among 23,241 genes, which we predicted were on the human genome, the number of the genes, which we predicted to be a reliable gene, was 16,754. About the analysis result, including the identification of the number of the genes, we reported it to Wakamatsu, A. et al. [15].

We thought that it was necessary to acquire the expression profile about every transcription product, protein-coding transcript, which encoded human protein, for analyzing the influence that the change of these gene expression levels gave to a gene function. A pattern and an expression level of the mRNAs in each gene were fairly different. Therefore, for examining a gene function and the correlation of the expression level, we selected genes by the overall expression level on every gene region.

We analyzed the variety of the mRNA using approximately 1,460,000 5'-ESTs of FLJ cDNA, which we acquired, mainly until now. We were able to acquire considerable knowledge about the varieties of the transcription start site (TSS) and the amino acid sequence of the N-terminal side, because it was the data which arrested the TSS that manufactured it by the improved oligo-capping method precisely, and those 5'-ESTs were sequenced to have length of approximately 500 bases [12-17]. There is the first exon variation (FEV), which is one type of alternative N-terminus [Figure 2-A] caused by the variation of TSS [18]. We found the genes, which FEV showed the expression pattern that was tissue-specific, to a lot so far [15]. We thought that those results brought about a different protein-coding transcript using suitable TSS of each gene under a certain tissue condition and the situation, and there was the gene that might give a functional variation [19-21]. It is very important to elucidate a gene function by analyzing the correlation between such a function and the change of a splice pattern.

However, it was difficult to precisely predict AS, except for the N-terminal side, and those expression frequencies to have the characteristics that the ESTs of the FLJ cDNAs, which we used for analysis, which mainly specialized in 5'-sides of mRNAs until now. We still did not sufficiently analyze the variety of mRNA in the downstream region more than 500 bases from

the TSS. Therefore we analyzed AS, except for the N-terminal side, to elucidate the relationship between those changes and gene functions as described below. We thought that it was the suitable gene set, which we chose this time, for analyzing a change of AS in all CDS coding regions, because the gene set included a change of CDS as a result of classification in a change of N-terminal, internal and C-terminal sides of CDS. Using these genes, we decided to examine the relations between the change of the expression level of every AS and the gene function.

Then, we decided to exclude the gene, which was high in expression level of every region of it, from an analysis candidate. We thought the excluded gene, which had a high expression level constitutively expressed in the cell and/or quite frequently already understood the gene function by previous advanced analysis. At first we predicted the expression level about every gene locus from the total number of human cDNAs (human full length sequenced cDNAs in public DB, human RefSeq, human Ensembl) and human ESTs mapped with respect to the gene locus. We defined the total number of cDNAs and ESTs mapped with respect to the same gene locus as cluster size and made a histogram. Then we selected a gene for further analysis with a cluster size less than 500. By this selection, 14,382 genes were included in it, which occupied 85.8% of the 16,754 genes that we predicted to be reliable genes [Figure 1].

Using the number of FLJ 5'-ESTs mapped with respect to the same gene locus, we decided to sort the further analysis candidate genes. We acquired full length cDNAs from approximately 100 kinds of human tissues and cells to perform the functional analyses of the human gene. We constructed approximately 1,460,000 full-length cDNA resources said to be FLJ cDNA and performed a sequence analysis of 5'-ESTs, which averaged length was approximately 500bp. These resources and sequence analysis information would be a useful tool in a gene function analysis. Because most materials used for construction of FLJ cDNAs are commercially available for approximately 100 kinds of human tissues and cells, we were able to obtain RNA easily. Therefore we decided to sort the gene where we already had resources and information. Then we defined the number of 5'-ESTs derived from FLJ cDNAs mapped onto the human genome with respect to the same gene locus as the FLJ 5'-EST size and then made a histogram. Using this result, we decided to select genes with FLJ 5'-EST size more than five. By this selection, 9,907 genes were included in it, which occupied 59.1% of 16,754 genes that we predicted to be reliable [Figure 1].

We predicted the CDS of the protein-coding transcript produced from the same gene locus and classified the CDS according to the result. Then we sorted the classification result for the purpose. In the gene functional analysis, we thought that it was particularly important to analyze the variety of the protein-coding transcript rather than the variety of mRNA. Therefore, we excluded CDSs, which a variation by AS existed in the noncoding region (UTR) or was predicted to be completely matched in CDS, from an analysis object about the gene. As a result, the number of genes meeting the condition that their protein-coding transcripts produce CDS of different plural kinds, is 9,323 genes. These genes occupied 55.6% of 16,754 genes that we predicted to be reliable [Figure 1].

Furthermore, we sorted the genes based on the number of protein-coding transcripts produced from the same gene locus. In AS, the mature mRNA is produced by changing the part and the combination of exons of the immature mRNA. In this complicated process splicing eliminates an unnecessary part, then the different plural number class of mature mRNAs is produced. In other words the number of mRNA, which can be produced theoretically by AS, is enormous, but the kinds are different in every gene. We thought that it would be difficult to analyze exhaustive gene expression, corresponding to the combination of a too complicated

protein-coding transcript. Therefore we predicted complexity of AS of the genome region and sorted out the results from the number of protein-coding transcripts produced from the same gene locus. Then we selected the gene with the number of predicted protein-coding transcripts less than ten. The gene to meet was among 6,297 genes, and held a condition 37.6% of 16,754 genes that we predicted to be reliable [Figure 1].

Figure 1. Procedure for the identification of candidate genes. Outline of our gene-characterization method from human full-length cDNAs and ESTs mapped to the human genome. EST, expressed sequence tag; CDS, coding region. “Human genes (high reliability category)”, 16,754 genes, were shown in Wakamatsu, A. et al. [15].

We obtained variation results produced in CDS by similarity searching for all protein-coding transcripts produced from the same gene locus using Align, similarity analysis software by Blastn and Blastp, and then manually evaluated the results as to what kind of CDS by AS was produced from that. After that each gene was classified by the splice pattern that we should have paid attention to. In this evaluation, low reliability patterns predicted in CDS were eliminated. These include patterns in which the immature mRNA and intron, was included. We also eliminated unreliable patterns caused by substitution and point mutation. By this evaluation, we selected 3,598 genes, which occupied 21.5% of 16,754 genes that we predicted to be reliably suitable for variety analysis of the mRNAs. In 3,598 genes, 5,983 patterns were found as a splice pattern, where we should have paid attention [Figure 1].

Then we classified the five kinds of splice patterns we found [Figure 2-A] by paying attention to the splice kind and the CDS region that thereby changed. As a result, the first pattern, “1: Alternative N-terminus”, was 1,408 patterns [Figure 2-B]. In this pattern, there is TSS as shown in Figure 2-A on exon, which is different from TSS of the known full-length cDNA, and is equivalent but alternative to the N-terminal side with the translation start point by the splicing patterns caused by different TSS. The fifth pattern, “5: Alternative C-terminus”, a C-terminal side is alternative and to change CDS, was 1,030 patterns [Figure. 2-B]. About another pattern, “2, 3 and 4: Alternative internal region”, that both N terminal and C-terminal

sides did not change but the internal region was alternative [Figure 2-A], had 3,545 patterns [Figure 2-B]. The pattern, “Alternative internal region”, was classified to three kinds [Figure 2-A], Type 1, 2 and 3, with different types of CDS regions. We classified that type 1 was an N terminal of CDS changed, type 3 was a C-terminus of CDS changed, and type 2 was a pattern except for type 1 and 3 [Figure 2-A]. As a result, we were able to classify in 677, 2,236, 632 patterns, respectively [Figure 2-B].

Figure 2. Classifications of selected 3,598 genes based on mRNA diversities. (A) Types of alternative splicing of protein-coding transcripts. Boxes, exons; black lines, introns; black boxes, coding regions; white boxes, untranslated regions. (B) Classifications of 5,983 patterns based on types of alternative splicing. (C) Categorization of 5,983 patterns by regions of alternative splicing. (D) Classifications of selected 3,598 genes by results of categorization.

From a gene, a multiple protein-coding transcript was produced by AS, but we thought that a protein-coding transcript, which was derived by stimulation and changed an expression level, was important to elucidate what region of the gene was often expressed by AS. For example, a possibility is when AS happens a lot to an N terminal end, that the gene is regulated by transcription. In addition, both ends do not change, but an expression level fluctuation is related to the presence of the gene functional domain, which is caused by having the exon or not in the internal region. In this case we think that the possibility that having the exon or not plays an important role for the change of the gene function. Therefore for analysis of AS data as to what kind of exon region of the mRNA was expressed and affected the change of the expression level, we decided to classify five kinds of patterns in three categories by paying attention to the region that had a change in CDS. Category A, change N-terminal region of CDS, which was the first category, combined two kinds of patterns, “1: Alternative N-terminus” and type 1 of “2: Alternative internal region” [Figure. 2-C]. The pattern classified in this group was 2,085 patterns [Figure. 2-C]. Category B, change internal region of CDS, which was the second category, consisted only of one kind of pattern, type 2 of “3: Alternative internal region” [Figure. 2-C]. The pattern classified in this group was 2,236 patterns [Figure. 2-C]. Category C, change C-terminal region of CDS, which was the third category, combined two kinds of patterns, type 3 of “4: Alternative internal region” and “5: Alternative C-terminus” [Figure. 2-C]. The pattern classified in this group was 1,662 patterns [Figure. 2-C].

Finally, with the three categories that we classified, we analyzed the AS pattern number to be about 3,598 genes to clarify what category deserved attention. Depending on a gene, plural AS happened, and the gene sorted in all three categories was exposed. As a result, Category A, “change N-terminal region of CDS; CDS, N-end”, category B, “change internal region of CDS; CDS, internal”, and category C, “change C-terminal region of CDS; CDS, C-end”, were calculated to be 1,651, 1,732 and 1,362 genes, respectively [Figure 2-C&D].

CONSTRUCTION OF THE CUSTOM DNA MICROARRAY FOR ANALYSIS OF MRNA VARIATION

We decided to perform a new construction of a custom DNA microarray for analyzing the expression pattern of every splice pattern, which could be analyzed to compare 5,983 splice patterns of 3,598 genes. We used a Roche NimbleGen multiplex array [4-plex format (4x72K)]. On this array, the probe length was 60 bases. Therefore, using 3,598 genes, we tried to identify a specific sequence region of every protein-coding transcript, which was necessary for a probe design. But a small amount of genes was not able to find the specific sequence region that was necessary for the design of the probe because the sequence length of the exon had a short. As a result, 3,413 genes were selected from 3,598 genes as the analysis candidates for exhaustive gene expression analysis of AS regions. To the 3,413 genes, we constructed the probes which assumed the specific target regions for the expression analysis for every AS pattern. Furthermore, we designed the probe to assume a common region shared in all protein-coding transcripts to be able to analyze an overall expression level of the gene. As a result, we identified 14,676 sites of specific sequence regions based on 8,672 cDNAs, which were selected as representative and alternative splicing variants from the consisted cDNAs of 3,413 genes, to analyze the expression frequency, and designed 48,388 probes in total in the regions

by basically using three kinds of probes for each site. We extracted the probe pair, which could compare AS patterns by the probes, which were specifically manufactured in AS patterns from there. As a result, from about 3,413 genes, we understood that we could compare the expression frequency of 5,784 AS patterns using probes of 5,784 pairs. Then we analyzed the AS pattern number of about 3,413 genes in the same way as the above-mentioned gene sets, 3,598 genes. As a result, Category A, “change N-terminal region of CDS; CDS, N-end”, category B, “change internal region of CDS; CDS, internal” and category C, “change C-terminal region of CDS; CDS, C-end”, were calculated to 1,520, 1,692 and 1,346 genes, respectively.

ANALYSIS OF ALTERNATIVE SPLICING USING NT2 CELLS INDUCED NEURONAL DIFFERENTIATION BY RETINOIC ACID

Using the custom DNA microarray, which we built, we decided to analyze the relations between a variety of the mRNA and the gene function. The genes were identified so that the expression levels were fluctuated by all-trans retinoic acid (RA) treatment using NT2 pluripotential human embryonal carcinoma cell, known as the NT2/D1 cell. This cell line is known so that neuronal differentiation is induced by treatment with RA [22]. Under the RA levels, which are able to cause neuronal differentiation, we understand that cell growth is not inhibited on this instance [22]. Furthermore, we are able to identify that all of them come from environmental factors, if the cultured cells change by RA induction and also by a variety of the mRNA changes [23-24]. Each stage of these cultured cells is one group with the same genetic background. AS is said to be important to the mammalian nervous system, when an important change occurs concerning neuronal differentiation such as cell differentiation, axon induction, neurite formation is regulated by AS [25].

We analyzed the change of the expression level for 35 days using NT2 cells after RA induction by the custom DNA microarray, and gathered analysis results of six time point samples, 0, 1, 2, 7, 14 and 35 days, which were listed below them sequentially with 0-day, 1-day, 2-day, 7-day, 14-day and 35-day, respectively [Figure 3-A]. Two kinds of independent experiments were performed. We prepared and repeated the schedule to subculture the samples of four kinds, 0-day, 1-day, 2-day and 7-day, as the first analysis (test 1) [Figure 3-B]. Two kinds of independent experiments were performed. We prepared and repeated the schedule to subculture the four kinds of samples, 0-day, 7-day, 14-day and 35-day, as the second analysis (test 2) [Figure 3-B]. From reproducible evaluation (results not shown) by the experiment, we prepared the analytical control to use a 0-day control sample of the first analysis (test1 0-day).

As a result, the expression level of a total of 2,171 sites of specific sequence regions, two of test2 0-day, 33 of test1 1-day, 85 of test1 2-day, 337 of test1 7-day, 357 of test2 7-day, 452 of test2 14-day and 905 of test2 35-day, satisfied our setting threshold 4-fold, compared with the control sample, test1 0-day, respectively. Then we merged those sites of specific sequence regions and as a result, 1,147 sites were picked up. In those we eliminated sites after evaluation then used another control sample, test2 0-day. Then we performed a cluster analysis for a selected 1,145 sites, as a result, the probes were clustered in order of RA induction time points, and two 0-day and two 7-day samples were each clustered with the same induction time points [Figure 3-C]. We evaluated genes of the selected 1,145 sites of specific sequence regions by analyzing the relationship between genes and probes designed on sites. As a result, we clarified

that they came from 583 genes. Because 2,513 sites of specific sequence regions, including sites on a common region, shared in all protein-coding transcripts were designed on those genes, as a result the expression level of 1,145 sites of specific sequence regions was changed by RA induction, but the remaining 1,368 sites were not changed by it.

Figure 3. Comparison of gene expression profiles of control and RA-induced NT2 cells by DNA microarray analysis. (A) Method for RA induction for NT2 cells. In response to all-trans retinoic acid (RA), NT2 cells differentiate towards a neuronal lineage. FUDR, 5-fluoro-2'-deoxyuridine; Urd, uridine; araC, cytosine beta-D-arabinofuranoside. NT2 cells shared the same genetic background; analyze changes in the mRNA diversity of genes following changes in an environmental condition (RA induction). (B) List of total RNAs used in this DNA microarray study. (C) Gene expression profiles of RA-treated cell data after filtering out the control cell data (0_t1). Columns and rows indicate RA time point samples and probes, respectively. Probes and samples are aligned in the order defined by the results of the clustering analysis. The color bar represents the grades of the relative expression levels: increase, red; decrease, blue.

In the 583 genes, we searched pairs of sites of specific sequence regions where we could compare the AS pattern, as a result, 452 genes were extracted. In the 452 genes, 1,003 sites of specific sequence regions showed the expression level change by RA induction, and 1,051 sites did not show it. Regarding the extracted 452 genes, we could compare the expression frequency of 857 AS patterns using 857 pairs of sites of specific sequence regions. Then we paid attention to each gene comparison contrast pair and analyzed it to see whether AS changed an expression level. As a result, in 614 pairs of the sites, the expression level of the pair of both or either changed, but the expression level of both pairs did not change into 243 remaining pairs. An expression level changed in about 614 pairs. We performed a comparison analysis to see whether the expression level was due to timing, and judged whether the expression profile was the same or different. As a result, the profiles of the expression level were different in about 480 pairs of sites, but the profiles were the same in about 134 of the remaining pairs.

We selected about 25 genes from those. We designed the specific DNA primers which could recognize protein-coding transcripts for comparing the AS patterns like custom DNA microarrays individually, and analyzed the expression profiles by the RA induction by real-time PCR using NT2 cells. As a result, because the technique was different, some genes showed that the degree of the change of the expression level by RA induction was different, however, all genes showed that the expression profiles of them by that were agreeable. The results of five genes, HOXA3, CRISPLD1, HOXA1, CYP2S1, and MTA3, were shown in Figure 4. We described below the analysis result examples, analysis 1-5, respectively. The results of another 20 genes, CDH6, CYP26B1, DENND5B, DMKN, DYSF, FAM65B, FGD4, FNDC5, GSTO2, HNF1B, LMCD1, LSAMP, MAPKAPK2, NCAM2, NEFM, RBP1, SEMA3C, SKAP2, ST3GAL5, and TFEC, were not shown here.

Analysis 1, HOXA3: The HOXA3 gene is one of the homeobox genes and it is said that it is a DNA-binding transcription factor [26-27]. The HOXA3 gene produced a protein-coding transcript having two kinds of different CDSs, NM_030661.3 and NM_153632.1. The two kinds of transcription products shared a homeobox domain, but were able to classify in Category A (CDS, N-end) because N-terminal regions are different [Figure 4-A]. We got a result of expression profiles by both real-time PCR and the custom DNA microarray by RA induction that an expression level was changed for two kinds of transcription products, and the rate of climb of two kinds of expression levels were different [Figure 4-A].

Analysis 2, CRISPLD1: CRISPLD1, cysteine-rich secretory protein LCCL domain containing 1, plays a role in NSCLP, nonsyndromic cleft lip plus palate, through the interaction with CRISPLD2 and folate pathway genes [28]. The CRISPLD1 gene produced protein-coding transcripts having two kinds of different CDSs, FLJ57290 and NM_031461.3. We classified this case in Category A (CDS, N-end) because two kinds of transcription products choose different TSS among different exons said to be FEV [Figure 4-B]. We got a result that an expression profile was as different as for an expression level changing as for two kinds of transcription products by both real-time PCR and the custom DNA microarray by RA induction, and the two kinds of expression profiles were different [Figure 4-B].

Figure 4. (Continued).

Figure 4. Quantitative analysis of expression of identified five RA-responsive genes by real-time PCR. Expression levels of two transcripts produced by AS from each gene were analyzed by DNA microarray (A1, B1, C1, D1 and E1) or by real-time PCR (A2, B2, C2, D2 and E2), and were represented in log₂ base. Name of the RA-responsive genes: (A) HOXA3, (B) CRISPLD1, (C) HOXA1, (D) CYP2S1, (E) MTA3. Boxes, exons; purple lines, introns; black boxes, coding regions; white boxes, untranslated regions; red or blue bars, detected regions; and numbers given in parentheses, genomic alignment positions. The real-time PCR data were normalized with respect to that of the human GAPDH.

Analysis 3, HOXA1: HOXA1 gene is a DNA-binding transcription factor in one of the homeobox genes [29-30]. The HOXA1 gene produced protein-coding transcripts having two kinds of different CDSs, NM_005522.3 and NM_153620.1. As for two kinds of transcription products, only NM_005522.3 was shown to have a homeobox domain by the difference of the splice pattern. We classified this case in Category B (CDS, internal) because the internal regions were different [Figure 4-C]. We got a result that an expression profile was as different as for an expression level changing as for two kinds of transcription products by both real-time PCR and the custom DNA microarray by RA induction, and the two kinds of expression profiles were different [Figure 4-C]. But the degree of the change was slightly different by experiment technique.

Analysis 4, CYP2S1: CYP2S1 encodes a member of the cytochrome P450 superfamily of enzymes [31]. The cytochrome P450 proteins are monooxygenases which catalyze many reactions involved in drug metabolism and synthesis of cholesterol, steroids and other lipids. This protein localizes to the endoplasmic reticulum [31]. The CYP2S1 gene produced protein-coding transcripts having two kinds of different CDSs, FLJ52866 and NM_030622.6. We classified this case in Category B (CDS, internal) because internal regions were different [Figure 4-D]. We got a result that an expression profile was as different as for an expression level changing as for two kinds of transcription products by both real-time PCR and the custom DNA microarray by RA induction, but the two kinds of expression profiles were the same [Figure 4-D].

Analysis 5, MTA3: Metastasis-associated protein (MTA3) is a constituent of the Mi-2/nucleosome remodeling and deacetylase (NuRD) protein complex that regulates gene expression by altering the chromatin structure and is able to facilitate cohesion loading onto DNA. The biological function of MTA3 within the NuRD complex is unknown [32]. The MTA3 gene produced protein-coding transcripts having two kinds of different CDSs, FLJ45312 and NM_020744.2. We classified this case in Category C (CDS, C-end) because the C-terminal regions were different [Figure 4-E]. We got a result that an expression profile was as different as for an expression level changing as for two kinds of transcription products by both real-time PCR and the custom DNA microarray by RA induction, and the two kinds of expression profiles were different [Figure 4-E].

Regarding the genes we selected in this way, we understood that we could cover data about the mRNA variations of genes by AS using the custom DNA microarray since probes were designed at sites of specific sequence regions. If data about mRNA variations of genes by AS could be accumulated using this approach, we thought that we would be able to elucidate the mechanism that an expression level of multiple mRNAs, produced from the same gene, was changed by response to various factors and then the gene functioned depending on the response to those. We also thought that it was important for new function elucidation.

ANALYSIS OF RELATIONSHIP BETWEEN mRNA VARIATION BY ALTERNATIVE SPLICING AND THE GENE FUNCTION

Finally, for analyzing the relationship between the variety of mRNA and the gene function, about 452 genes responsive to RA, which were identified as having expression level changed

protein-coding transcripts by the expression analysis, were analyzed as to what kind of region was changed by AS. 857 AS patterns were built in 452 genes responsive to RA [Figure 5-A].

(A)

Category	Patterns (3,598 genes)	Patterns (452 RA induced genes)	Expression level by RA induction		Expression profile by RA induction	
A (CDS, N-end)	2,085	273 (13.1%)	change	155 (7.4 %)	differ	134 (6.4%)
			not change	118 (5.7 %)	same	21 (1.0%)
B (CDS, internal)	2,236	339 (15.1%)	change	259 (11.6%)	differ	178 (8.0%)
			not change	80 (3.6%)	same	81 (3.6%)
C (CDS, C-end)	1,662	245 (14.7%)	change	200 (12.0%)	differ	168 (10.1%)
			not change	45 (2.7%)	same	32 (1.9%)

Figure 5. Quantitative evaluation of expression of selected 3,598 genes by DNA microarray analysis using NT2 cells. Evaluation of expression profile of 452 RA induced genes by DNA microarray analysis.

Then we analyzed the AS patterns of 452 genes responsive to RA induction according to a category. AS pattern number of Category A (CDS, N-end), Category B (CDS, internal) and Category C (CDS, C-end) was 273 (13.1%), 339 (15.1%) and 245 (14.7%), respectively [Figure 5-A]. From this result, the distribution of 857 AS patterns of 452 responsive genes selected by the expression change by RA induction did not differ much with that of 5,983 patterns of 3,598 genes for the analysis candidates [Figure 5-A].

After that analysis, we divided the AS patterns into those that did not show a change and those that showed an expression level change by RA induction [Figure 5-A]. As a result, in Category A (CDS, N-end) where the N-terminal side of CDS region changed, the AS patterns that the expression levels changed were 155 (7.4%) [Figure 5-A]. Then we compared the expression profiles of the 155 AS patterns where the expression levels changed by RA induction; as a result 134 (6.4%) showed different profiles [Figure 5-A]. In Category B (CDS, internal) where the internal region of CDS region changed except for the N-terminal and C-

terminal regions, the AS patterns that the expression levels changed were 259 (11.6%) [Figure 5-B]. Then we compared the expression profiles of the 259 AS patterns where the expression levels were changed by RA induction, and as a result 178 (8.0%) showed different profiles [Figure 5-B]. In Category C (CDS, C-end) where the C-terminal side of CDS region changed, the AS patterns that the expression levels changed were 200 (12.0%) [Figure 5-A]. Then we compared the expression profiles of the 200 AS patterns where the expression levels were changed by RA induction, and as a result 168 (10.1%) showed different profiles [Figure 5-B]. By the distribution of the AS patterns of 614 pairs where the expression levels changed by RA induction from this result, the rate of AS patterns classified in the category of Category A (CDS, N-end) was fewer than that of another two categories [Figure 5-B]. In the evaluation of every gene, there were fewer genes distributed over Category A (CDS, N-end) with the genes that the expression levels changed than the other two categories [Figure 5-A].

From our previous studies regarding AS in the N-terminal region [15, 18-21, 23, 24], we thought that there was only a strong correlation between the mRNA variation of the N-terminal region of protein-coding transcript by AS and the gene function according to the gene expression pattern. However, from the results described above, a lot of mRNA variation by AS in both the internal and C-terminal regions of protein-coding transcripts also existed, and some of those were correlated with an expression level change, which sometimes induced a functional alteration of the gene, such as by RA induction [Figure 5-B]. From these results, we would have to use human full-length cDNA resources and the sequence analysis information, which we obtained during previous research, for further sequence analysis of both the internal and C-terminal regions of protein-coding transcripts using next generation DNA sequencing system. Further analysis is necessary regarding AS for more detailed gene function analysis using full-length cDNAs.

CONCLUSION

One of the most important prerequisites for understanding the functions of genes is to analyze mRNA diversity. At least 70% of all human genes produce multiple transcripts by AS [3, 8]. Genes could produce multiple protein-coding transcripts by AS for generating biological and functional diversity.

We sequenced approximately 55 thousand human full-length cDNAs and approximately 1.45 million 5'-ESTs from human cDNA libraries constructed by the oligo-capping method for gene functional analyses [12-15]. The studies indicated that a single gene could utilize AS for tissue-specific transcription [15]. We also constructed the FLJ Human cDNA Database [15], <http://flj.lifesciencedb.jp>, which would be useful in analyzing the diversity of protein-coding transcripts. Furthermore, we found a close relationship between the predicted function of a gene and its tissue-specific expression, implying that the gene was transcribed into an appropriate transcript according to the needs and circumstances [15]. However, we were unable to distinguish whether the observed expression pattern was associated with the genetic or the environmental risk factors, primarily because the tissues and cell lines used in our analyses were not derived from one person.

Therefore, we used human NT2 cells for analyzing mRNA diversity [23-24]. This cell line is a good model for the embryonic development as well as for tumor cell differentiation. In

response to RA, NT2 cells differentiate towards a neuronal lineage with associated loss of cell growth and tumorigenicity [22]. Because these cells shared the same genetic risk factor, we were able to analyze changes in the mRNA diversity of genes as a result of RA induction, an environmental risk factor [23-24]. We believe the mRNA diversity and gene function are correlated [23-24, 33], and therefore, it is imperative to understand this relationship in order to identify the genes that are specifically involved in neurodifferentiation. This point of view could be expanded to elucidate other phenomena.

Accumulating more data on the mRNA diversity of genes using approaches similar to what we have described above will not only reveal the underlying mechanism by which genes produce specific protein coding transcripts in response to various factors, but will also contribute to the discovery of new gene functions. Moreover, identification of the risk factors responsible for the mRNA diversity would be an important step for gene function analyses and identifying candidate genes as novel targets for the development of new drugs and therapies.

Chapter 26

ALTERNATIVE SPLICING IN HUMAN IMMUNE SYSTEM AND AUTOIMMUNE DISEASES

Xiang Guo

Translational Sciences, MedImmune, LLC, Gaithersburg, MD, US

ABSTRACT

Alternative splicing of pre-messenger RNA is nearly universal, involving more than 90% of human genes. It's an essential step in gene expression and responsible for much of the proteome diversity in mammalian genomes. The immune system requires a great diversity of functional proteins and immune cells need to respond to various foreign invasions rapidly. Alternative splicing provides one more layer of regulation that is essential for the function of human immune system. Many immune genes have been found to undergo alternative splicing, which plays an important role in the regulation of immune cell activation and function. Dysregulated splicing has been shown to be involved in various immune disorders, such as systemic lupus erythematosus (SLE) and rheumatic arthritis (RA). It may be a direct cause of the disease, or a modifier of disease susceptibility and severity. Further understanding of how alternative splicing may be used as a general mechanism in immune response is essential for our research in the pathophysiology of autoimmune diseases and development of new therapeutics for those diseases. This chapter provides an updated review about alternative splicing in human immune system as well as the relationship between dysregulated splicing and autoimmune diseases, particularly SLE and RA.

The immune system is a complex network of leukocytes, tissues, and organs that was designed to defend the body against foreign invasions. A sufficient diversity and flexibility is required for a functional immune system to ensure rapid adaption and response to changing environment in a quick and precise way. The great diversity of immune system can partly be achieved by gene regulation. While there have been many reports showing the crucial role of transcriptional regulation in the immune system, much less is known about another mechanism of gene regulation, namely alternative splicing.

Alternative splicing of per-messenger RNA is nearly universal, involving more than 90% of human genes [1]. It's an essential step in gene expression and responsible for much of the proteome diversity in mammalian genomes. Distinct mRNA transcripts can be generated from a single gene locus by including or excluding exons during post-transcriptional processing. Then, variant transcripts may produce proteins with different functional domains in different cell types and cell states. Alternative splicing can also regulate gene expression levels by eliminating microRNA binding site or through nonsense mediated decay.

Dysregulated splicing has been demonstrated in various diseases including autoimmune disorders [2]. It may be a direct cause of the disease or a modifier of disease susceptibility and severity. Investigation of the roles alternative splicing may play in autoimmune diseases is essential for the understanding of disease pathophysiology and development of new medicine for those diseases. This chapter summarizes the current knowledge about splicing in human immune system and autoimmune diseases.

ALTERNATIVE SPLICING AND IMMUNE CELL FUNCTION

Alternative splicing is regulated in a cell specific manner to control the immune response. It helps to shape the course and outcome of lymphocyte activation, which adds another layer of complexity for innate and adaptive cellular immunity. Multiple genome-wide analyses have demonstrated the crucial role of alternative splicing in modulating the activation threshold and maintaining homeostasis of lymphocytes, particularly T cells [3-7].

T cells respond to antigen challenge and express a plethora of proteins to initiate a broad network of signaling cascade, which then results in changes in cell migration, cytokine secretion, and other effector functions. Both transcriptional and splicing regulations have been shown to influence T-cell biology, but they appear to do so through distinct functional pathways. In a recent RNA-Seq study using PMA stimulation of human T-cell line to mimic mature TCR signaling, a similar percentage of genes exhibited splicing changes as transcriptional changes but no significant overlap was observed between two sets of genes. Those signal-responsive splicing events are involved in mediating critical T-cell effector functions, such as cell signaling, development, and trafficking. The vast majority of these genes are also regulated in a similar pattern in response to antigen challenge of primary CD4⁺ or CD8⁺ T cells [3].

The short-term changes that happen after TCR activation involves alternatively spliced genes that encode immediate T-cell effector functions. Intracellular protein kinases (PTKs) are first activated after antigen recognition by the TCR. Two different isoforms of the SRC-family PTK FYN have different efficiency at mediating TCR-induced calcium mobilization [8]. Virally infected T cells show increased expression of the low efficiency isoform, FYNB, which may be beneficial to the virus by decreasing T cell activation [9]. Cell-surface adhesion molecules are also crucial to early events in T-cell activation. CD44 is a cell surface glycoprotein involved in lymphocyte activation and homing. It has 10 variable cassette exons, which can produce a large number of CD44 variant forms. The smallest isoform without all variable exons are mainly expressed in naïve T cells, while multiple longer isoforms are expressed in activated T cells [10, 11]. Antibodies specific for those longer CD44 variants can

block *in vivo* activation of T cells, which demonstrates the crucial role of CD44 splicing for T-cell function [10].

T cell activation requires both TCR stimulation and CD28 co-stimulation. While TCR stimulation has been shown to cause both transcriptional and splicing changes of a large number of genes, very few genes demonstrate CD28 specific changes in gene transcription. In contrast, CD28 co-stimulation leads to profound changes in alternative splicing in naïve T cell upon their activation, with nearly 8 times as many genes being regulated through alternative splicing as gene transcription [4].

Once a T cell has carried out its required effector functions, prolonged T cell activation has to be blocked to prevent hyper-proliferation or hyperactivity of the immune response. Many genes that only display alternative splicing following prolonged activation encode proteins important for homeostasis or development of immunologic memory. CD45 is a transmembrane protein tyrosine phosphatase that is essential for TCR signaling. The smaller isoform CD45R0 shows weaker response to TCR ligation than the larger isoform CD45 RA. The change from CD45RA to CD45R0 after T-cell activation functions as a feedback mechanism to reduce prolonged TCR signaling [12]. Cytotoxic T-lymphocyte antigen 4 (CTLA-4) is a protein receptor that inhibits the CD28-dependent co-stimulatory signal. The stimulation of T cells induces the inclusion of a cassette exon that encodes the transmembrane domain of CTLA-4, so the expressed CTLA-4 protein is membrane-bound to prevent hyperstimulation of T cells [13]. Other splicing events involved in late activation of T cells include heterogeneous nuclear ribonucleoprotein D0 (AUF1) and lymphoid enhancer-binding factor 1 (LEF1) [14].

Regulatory T cells (Treg) can suppress proliferation and effector function of CD4⁺ T helper cells. They are critical for the negative regulation of immune response and the prevention of autoimmunity. Multiple differentially expressed splice variants have been detected between resting and activated cells, such as interleukin receptor 1 associated kinase (IRAK1), SAM68, and IL2RA [6]. The truncated isoform IRAK1c lacks kinase activity and it functions as a dominant negative to suppress NF- κ B activation [15]. The specific expression of IRAK1c in activated Treg cells may regulate TCR signaling and the subsequent inflammatory response.

Splicing regulation is also evident in the function of other immune cells. Significant splicing changes have been detected in CD19⁺ B cells activated by anti-CD40/IL2/IL10, although the total number of alternatively spliced genes is less than that detected in CD2⁺ T cells activated by anti-CD3/CD28 antibodies [5]. Human neutrophils express several splice variants of functional genes such as Fc α receptor [16], caspase-8 [17], glucocorticoid receptor [18], phospholipase D [19], glutaredoxin 1 [20], GM-CSF receptor α [21], and pantetheinase family proteins [22]. Adenosine is an endogenous inhibitor of neutrophil functions via binding to four subtypes of adenosine receptors: A1, A_{2A}, A_{2B}, and A3. It also delays neutrophil apoptosis, which may be involved in rheumatoid arthritis (RA) pathophysiology [23]. The A_{2A} receptor mRNA is up-regulated upon lipopolysaccharide (LPS) stimulation of human neutrophil, in which the differential splicing of 5'-UTR plays an important regulatory role. A_{2A} receptor transcripts with long 5'-UTRs are mainly expressed in resting neutrophil, whereas transcripts with short 5'-UTRs predominate in stimulated neutrophils which displayed higher translation efficiency than the longer variants [24]. Dendritic cells (DCs) are critical initiators of innate immunity and play a key role in controlling the magnitude and quality of adaptive immune responses. A recent study has demonstrated widespread alternative splicing events and splicing factor transcriptional signatures induced by an *E. coli* challenge to human DCs. Novel

isoforms have been validated for interferon regulatory factor 4 (IRF4), cyclin-dependent kinase inhibitor 3 (CDKN3), and 6 other genes in DCs following exposure to a pathogen [25].

ALTERNATIVE SPLICING AND CYTOKINE RESPONSE

Immune cells communicate with one another by releasing and responding to chemical messengers called cytokines. Splice variants of many cytokines have been shown to be functional antagonists of their corresponding wild-type cytokines. Cellular location may also be different for splice variants of the same cytokine, which can be soluble or membrane bound. Alternative splicing of cytokines, cytokine receptors, and signal transduction molecules has been shown to be an important regulatory mechanism for the human immune system.

IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 are a family of structurally related cytokines whose type I cytokine receptors share the identical IL-2 receptor γ chain (CD132). These γ c-dependent cytokines are involved in survival, proliferation and effector function of activated T cells. Two IL-2 variants that omit either exon 2 or exon 3 display an antagonistic activity and inhibit wild-type IL-2 binding to IL-2 receptors, which may be involved in acute rejection of transplantation [26, 27]. The IL-4 variant without the second exon (IL-4 δ 2) also exhibits an antagonistic activity to the wild type IL-4. Increased level of IL-4 δ 2 has been found in patients with systemic sclerosis and atopic asthma, which may be used as a diagnostic marker for these diseases [28, 29]. The α subunit of IL-2 receptor (CD25) may undergo dysregulated splicing in adult T-cell leukemia (ATL) patients to generate a short peptide without the conventional transmembrane domain [30]. The soluble isoform of IL-4 receptor α is coded by exons 3-8 that lacks the exons for the trans-membrane and intracellular regions. Sequence variations around exon 8 seem to be responsible for the selective splicing of IL-4 receptor α in allergic asthma patients [31]. Splice variants of IL-7, IL-7 receptor, IL-9 receptor, IL-15, IL-15 receptor, and IL-21 have all been identified and their functional relevance in human immune system remains to be further elucidated [32-37].

IL-6 has diverse functions in the immune system and it is implicated in a wide variety of inflammation-associated disease states. The splice variant of IL-6 without exon 4 acts as a dominant negative form of full-length IL-6. It seems to compete with native IL-6 for the interaction of IL-6R α (CD126), thus block IL-6R β (CD130) mediated signaling [38]. Another IL-6 variant produced by renal cell carcinoma also displayed IL-6 antagonist properties [39]. In addition, alternative splicing gives rise to soluble form of IL-6 receptor, which has been shown to be increased in various pathological conditions including rheumatoid arthritis and viral diseases [40].

Similar to IL-6 receptor, the receptors for granulocyte macrophage colony-stimulating factor (GM-CSF), IL-3, and IL-5 are type I cytokine receptors consisting of a ligand-specific α subunit and a common β subunit (CD131). Alternative splicing of GM-CSF receptor α subunit (GMR α) produces several soluble proteins, including one variant with a 102 nucleotide insertion derived from an Alu DNA repeat element [21] and another with exclusion of the exon encoding the transmembrane domain [41]. These soluble proteins act as functional antagonists of GM-CSF *in vitro*, but their biological roles *in vivo* are not yet clear [42]. IL-5 receptor α subunit (IL-5R α) has a soluble isoform-specific exon whose transcription exerts an antagonistic effect on eosinophil proliferation and differentiation. The balance of soluble and membrane-

bound IL-5R α regulated by splicing may play important role in IL-5 related diseases such as asthma and eosinophilic syndromes [43].

The class 2 cytokines consist of IL-10, IL-19, IL-20, IL-22, IL-24, IL-26, interferons, and interferon-like molecules. IL-24 is also known as melanoma differentiation-associated gene 7 (mda-7) since it is discovered as a tumor suppressor protein. Isoforms of IL-24 have differing levels of effectiveness in inducing apoptosis of cancer cells [44], and the loss of one isoform MDA-7S has been associated with metastatic melanoma [45]. IL-10 variant was also observed in cancer patients and its expression has been related to favorable response to chemotherapy [46]. The receptors for class 2 cytokines are similar to type I cytokine receptors except they do not possess the signature sequence WSXWS that is characteristic of type I receptors. It has been suggested that splicing of IL-20 receptor may be associated with the exacerbation of lupus nephritis [47].

Interleukin 1 receptor antagonist (IL-1Ra) competes with IL-1 α and IL-1 β for the binding sites of type I IL-1 receptor (IL-1RI), and acts as one of the control mechanisms of IL-1 signaling. Type II IL-1 receptor (IL-1RII) is a decoy receptor that inhibits the activity of its ligands – IL-1 α , IL-1 β , and IL-1RI. Cell-specific production of IL-1Ra splice variants has been demonstrated in human neutrophil and monocyte. While both LPS-stimulated neutrophils and PBMC synthesize soluble IL-1Ra and intracellular IL-1RaII (16 KDa), only PBMC transcribe and translate intracellular IL-1RI (18 KDa) [48]. Alternative splicing of IL-1RII generates soluble and membrane-bound forms of IL-1RII whose differential induction has been correlated with clinical glucocorticoid responsiveness in patients with autoimmune inner ear disease [49].

In addition to the production of cytokines and cytokine receptors, various spliced variants of intracellular molecules are involved in the signal transduction from a cytokine receptor to downstream targets. JAK/STAT pathways mediate signaling from a long list of membrane receptors including interferon, interleukin, hematopoietic and growth factor receptors. Signal transducers and activators of transcription (STAT) proteins are the products of at least seven genes, and additional isoforms of these gene products result from alternative splicing and post-translational processing. The resulting family of transcription factors generates a wide potential for activation and regulation of target genes and gene combinations with far-reaching consequences for development, cell growth and homeostasis [50, 51]. Another example is related to alternative splicing of IL-1R-associated kinase I (IRAK1) and myeloid differentiation primary-response gene 88 (MyD88). The smaller isoform of IRAK1 lacks kinase activity, which may function as part of a negative-feedback loop in which IRAK1 function is decreased in response to IL-1 stimulation [52, 53]. Full-length MyD88 protein recruits IRAK4 to activate IRAK1 in response to IL-1 binding, while the short isoform of MyD88 inhibits IL-1 signaling [53].

DYSREGULATED SPLICING IN AUTOIMMUNE DISEASES

Splicing regulation is critical for the normal functioning of human immune system, and dysregulated splicing has been shown to play an important role in various immune disorders. Many mutations or epigenetic changes may alter alternative splicing of disease-associated genes thus exerting their deleterious effects on immune response. Aberrant splicing may be a direct cause of the disease, or a modifier of disease susceptibility and severity. Those splice

variants may also be responsible for the non-responsiveness or drug resistance of patient subsets to treatments of autoimmune diseases [54].

Glucocorticoids regulate a variety of biological processes on virtually all physiological organ systems, and they have been used extensively as potent immunosuppressive agents in the treatments of many autoimmune and inflammatory disorders. However, insensitivity or resistance to glucocorticoids is often observed in patients taking these hormones. Such drug resistance may be partially explained by differential expression of two splice forms of glucocorticoid receptor (GR) [55]. The classic receptor variant GR α mediates most of the known functions of glucocorticoids, while the other variant GR β exerts a dominant negative effect upon the GR α -induced transcriptional activity. The latter isoform GR β has been shown to be highly expressed in glucocorticoids-resistant patients, which may block GR α -induced transcriptional activity causing the resistance to hormone treatment in those patients [56]. Proinflammatory cytokines such as IFN- α may be responsible for the splicing regulation of GR in lymphocytes or neutrophils from patients with autoimmune conditions [57-59]. In addition, one SNP in the 3'-UTR of GR β mRNA seems to increase its stability thus causing increased expression GR β protein. This SNP has been associated with increased risk of rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE), suggesting the direct involvement of GR variant in the pathogenesis of rheumatic diseases [60].

SLE is a complex and heterogeneous autoimmune disease with a strong genetic component. Its pathophysiology involves a number of immunological pathways, such as the type I interferon pathway, B-cell signaling, cytokine production, and neutrophil function. Multiple susceptibility loci are already identified in genes participated in the function of those pathways, and some of them have been proposed to affect splicing.

Interferon regulatory factor 5 (IRF5) is a transcription factor that induces the transcription of interferon- α . There are more than 10 distinct isoforms of IRF5 with cell-specific expression, regulation, and function [61]. SLE patients express an IRF5 transcript variant signature that is distinct from healthy donors and associated with the IRF5-SLE H2 risk haplotype [62, 63]. This haplotype includes the T-allele of SNP rs2004640 that introduces a new donor splice site in the first exon [64], and the A-allele of SNP rs10954213 that provides an alternate polyA⁺ signal shortening the length of the 3'-UTR and enhancing IRF-5 stability [65].

The hallmark of SLE is the elevated production of auto-antibodies by B cells which leads to the formation of immune complexes causing tissue damage and chronic inflammation. B-cell scaffold protein with ankyrin repeats (BANK1) has been reported to be a susceptibility gene for SLE in Europeans, European-Americans, and Asians [66]. The non-synonymous SNP rs10516487 in BANK1 influences splicing efficiency by creating an exonic splicing enhancer site, and generates protein isoforms with differential self-association properties. The BANK1 variant with an increased self-assembly ability is highly produced in SLE patients, which could result in the more sustained BCR-mediated signaling in SLE. A T-cell marker CD5 was found to be expressed in B cells 30 years ago, and the CD5-positive B cell (B1) population has been considered to play a paradoxical role in SLE pathophysiology since then. The membrane expression of CD5 is regulated by alternative splicing of exon 1A and exon 1B. The full-length protein variant generated by exon 1A raises the threshold of BCR thus limits the response of auto-reactive B cells, while the truncated variant encoded by exon 1B remains in the cytoplasm. The truncated form is overexpressed in SLE patients, which leads to a decrease of CD5 cell surface expression and possible exacerbation of disease activity [67]. The pre-B-cell leukemia homeobox 1 (Pbx1) gene has a central role during development and

organogenesis. A novel splice isoform of Pbx1 has recently been found to express more frequently in the CD4⁺ T cells from lupus patients than from healthy controls. The presence of this variant correlates with an increased central memory T cell population, suggesting Pbx1 to be a novel lupus susceptibility gene that regulates T cell activation and tolerance [68].

Other aberrant splicing events identified in SLE include T-cell receptor ξ chain [69], CD72 [70], CD44 [71, 72], CTLA-4 [73], complement receptor 2 [74], Ras guanyl-nucleotide releasing protein 1 [75], leukocyte immunoglobulin-like receptor A2 [76], phospholipid scramblase 1 (PLSCR1) [77], and signalling lymphocyte activation molecule (SLAM) family receptors CS1 (CD319) and 2B4 (CD244) [78]. These examples identified by small-scale studies strongly suggested the importance of alternative splicing in SLE pathogenesis. A comprehensive evaluation of splicing regulation in SLE remains to be done, which shall greatly help us in understanding and management of this systemic autoimmune disease.

RA is a chronic inflammatory disorder that affects the body's joint and the extra-articular tissues of the skin, heart, and muscles. Increased flow of white blood cells into the synovium leads to inflammation which causes acute swelling and the destruction of cartilage and bone tissue in RA patients. Multiple pro-inflammatory cytokines, chemokines and growth factors play a fundamental role in its pathogenesis.

TNF- α is one of the most potent pro-inflammatory cytokines in RA, and anti-TNF α therapy has successfully controlled symptoms of many RA patients. However, about 25% to 30% of RA patients treated with TNF antagonists do not have any significant clinical response. Membrane-bound TNF receptors (TNFR1 and TNFR2) mediate TNF- α signaling, and their soluble forms may neutralize TNF- α in the circulation. A novel spliced variant of soluble TNFR2 (DS-TNFR2) has recently been identified to antagonize TNF- α action. RA patients with high levels of DS-TNFR2 had a prolonged therapeutic response to anti-TNF therapy and less radiographic progression than patients with normal levels [79].

Another potential biomarker of response to TNF- α antagonists is the soluble form of IL-7 receptor (sIL-7R) generated by alternative splicing of the full-length transcript. Transcripts for both membrane-bound (rIL-7R) and sIL-7R are over-expressed in synovial tissues of RA patients, and they are up-regulated by the addition of TNF- α and other pro-inflammatory cytokines in fibroblast-like synovial cells. However, mIL-7R protein was not detected on cell surface while sIL-7R levels were induced by those cytokines, indicating that sIL-7R is a marker of fibroblast. Strikingly, high baseline sIL-7R serum levels are significantly associated with poor response to TNF- α antagonist. It may qualify as a new biomarker of response to therapy in RA [80].

Similar to SLE, a large number of individual splicing events have been identified in RA by small scale studies while there lacks a comprehensive survey of splicing regulation in RA [81, 82]. Interestingly, multiple genes have been found to undergo aberrant splicing regulation in different autoimmune diseases. For example, increased CD44v6 expression on SLE T cells and RA monocytes has been shown to correlate with SLE and RA disease activity respectively. In contrast, CD44v3 expression was decreased on RA monocytes but increased on SLE T cells [72, 83]. Investigation of splicing regulation may reveal shared features and unique markers for different autoimmune diseases. In addition, therapeutic strategies may be developed to manipulate splicing for the treatment of SLE, RA, and other immune disorders [84].

SUMMARY

Further understanding of how alternative splicing may be used as a general mechanism in immune response is essential for our research in the pathophysiology of autoimmune diseases and development of new therapeutics for those diseases. Dysregulated variants may be developed as diagnosis, prognosis, pharmacodynamics, and predictive biomarkers for immune diseases. More importantly, certain isoforms of known disease targets may have unique epitopes within their extracellular region which would allow the development of specific monoclonal antibodies. Antisense technology may also be used to mediate alternative splicing for the treatment of different diseases [84].

The advent of high throughput RNA sequencing (RNA-seq) provides an unprecedented opportunity for the study of alternative splicing. It allows accurate quantitative measurements for alternative splicing levels and discovery of novel isoforms [85]. The ongoing improvements in technology and increased application of RNA-seq in immunology research shall greatly expand our knowledge in human immune systems and autoimmune diseases.

POLY(ADP-RIBOSYL)ATION REGULATES ALTERNATIVE SPLICING

Yingbiao Ji and Alexei V. Tulin*

Cancer Biology Program, Fox Chase Cancer Center, Philadelphia, PA, US

ABSTRACT

Poly(ADP-ribosyl)ation is a major post-translational modification performed by Poly(ADP-ribose) Polymerases (PARP1). PARP1 utilizes NAD as the substrate to synthesize a long linear and branching poly(ADP-ribose) (pADPr), ranging in length from 2 to 200 units of ADP-ribose. PARP1 can modify a variety of proteins by attaching pADPr to the target proteins in either a covalent or noncovalent manner. In this way, Poly(ADP-ribosyl)ation is involved in a number of biological processes, including transcription regulation, stress responses, and apoptosis. Recent studies have demonstrated that several splicing factors, including hnRNPs and S/R proteins, are poly(ADP-ribosyl)ated via noncovalent binding by PARP1. Here, we describe how poly(ADP-ribosyl)ation regulates alternative splicing by modulating the activities of these splicing factors. In addition, we discuss a possible role of PARP1 in coupling transcription with splicing.

INTRODUCTION

Alternative splicing (AS) greatly enhances the proteomic complexity of an organism with otherwise limited numbers of encoding genes in the genome [1]. For instance, the *Drosophila* Dscam (Down syndrome cell adhesion molecule) gene can produce 38,016 different isoforms through alternative splicing [2]. AS is achieved by spliceosomes that choose alternative 5' splicing sites (5'ss) or 3'ss to remove the intron of a pre-mRNA. A spliceosome is composed of five small nuclear RNA (snRNA) molecules and associated proteins, such as snRNPs [3]. The interaction between splicing regulatory elements (SREs) and transacting factors defines

* Corresponding Author's Email: Alexei.Tulin@fccc.edu (Alexei V. Tulin, Ph.D. Fox Chase Cancer Center, 333 Cottman Avenue Philadelphia, PA 19111; Tel: (215) 728-7408; Fax: (215) 728-2412).

the exact splicing sites to generate spliced variants. SREs include exonic and intronic splicing enhancers (ESSs and ISSs) and silencers (ESEs and ISEs). The two major groups of transacting factors, named hnRNPs and SR (serine-arginine-rich) proteins, bind to SREs and enhance or inhibit the recruitment of a spliceosome to the splice sites. Therefore, controlling the expression levels and activities of hnRNPs and SR proteins is critical for achieving tissue- or developmental-specific splicing regulation.

Poly(ADP-ribosyl)ation (PARylation) is a specific post-translational modification performed by Poly(ADP-ribose) polymerases (PARPs), which utilize NAD as the substrate to synthesize poly(ADP-ribose) polymer (pADPr) [4]. Although the PARP superfamily includes 17 members (PARP1-PARP17) in the mammalian genome [5], PARP1 enzymatic activity is responsible for producing 90% of pADPr products in cells [4]. PARP1 mainly modifies itself in a covalent manner through Glu/Asp and/or lysine residues in its automodification domain [6, 7]. In addition, automodified PARP1, or free pADPr, can bind to a variety of targets, including histones and other chromatin-associated proteins, in a noncovalent manner [8]. To reverse the protein modifications by PARylation, Poly(ADP-ribose) glycohydrolase (PARG) degrades pADPr to a single unit [9-11]. Because pADPr is a highly negatively charged, and often branching, macromolecule varying in size from two to up to 200 ADP-ribose, PARylation often dramatically changes the chromatin structure and thereby regulates transcription processes [4, 12, 13]. Recent studies have shown that the activities of hnRNPs and SR proteins can be regulated by PARylation to modulate alternative splicing [14-16]. In this review, we summarize how poly(ADP-ribosyl)ation regulates alternative splicing by modulating the activities of the splicing factors. In addition, we address a possible role of PARP1 in coupling transcription with splicing.

1. REGULATION OF ALTERNATIVE SPLICING BY PARYLATION

1.1. Interaction of hnRNPs with Poly(ADP-ribose)

It was first reported that pADPr could bind to human hnRNP proteins in a noncovalent manner via a conserved domain [14]. This domain represents a 20 amino acid-long segment located between two RNA-binding domains of hnRNPA1 and belongs to the first pADPr-binding motif identified in DNA-damage-related proteins [17]. A mass spectrometry analysis coupled with co-immunoprecipitation demonstrated that *Drosophila* hnRNPA1 (Hrp38) is associated with PARP1 *in vivo* [18]. It was also found that PARP1 could modify two hnRNP proteins (hrp38 and Hrp40) by noncovalent pADPr binding [16], suggesting that PARylation of hnRNPs is a conserved mechanism between mammals and *Drosophila* [14, 16]. Since PARP1-pADPr-hnRNP complex has been detected in *Drosophila*, it appears that automodified PARP1 interacts with hnRNP proteins *in vivo* [16]. Both overexpression of PARP1 and PARG loss-of-function mutation increase pADPr levels and also cause an increased level of PARylated hnRNPs in *Drosophila* [16]. Heat-shock treatment also enhances hnRNP PARylation by the induction of PARP1 activity [16, 19]. These results demonstrate that hnRNP PARylation is a post-translational modification which can be regulated at the genetic and physiological levels.

1.2. Inhibition of RNA-Binding Ability of hnRNP Proteins by PARylation

Both *in vivo* and *in vitro* experiments showed that PARylation inhibits the RNA-binding ability of hnRNP proteins [16, 20]. *Drosophila* Hrp38 is associated with the actively transcribed loci known as puffs in the polytene chromosomes found in salivary gland cells of the wild-type fruit fly [16]. In *Parg* mutants, Hrp38 dissociates from puffs and moves into the nucleoplasm, where Hrp38 appears to be highly PARylated [16]. Therefore, the observed dissociation of Hrp38 from most of the transcripts in the *Parg* mutant background is most likely triggered by accumulation of pADPr and overwhelming PARylation in the absence of PARG. In another line of evidence supporting this argument, Hrp38 was shown to reduce binding to one long noncoding RNA (Hsr ω -n) upon heat-shock treatment in the *Parg* mutant [16]. Hrp38 and Hrp40 dissociate from most transcripts and exclusively bind to this heat shock-induced noncoding RNA after heat shock [16, 21]. Since heat shock induces PARP1 activity and, hence, increases hnRNP PARylation [16], it has been proposed that PARylation acts as a molecular tool which moves hnRNPs from the chromatin to the nucleoplasm. In addition, it was observed that much smaller amounts of Hrp38 and Hrp40 were associated with this noncoding RNA in the *Parg* mutant compared to the wild-type animal after heat shock treatment [16], suggesting that PARylation inhibits the target-binding ability of hnRNPs. *In vitro* experiments based on the RNA electrophoretic mobility shift assay (EMAS) also demonstrated that pADPr binding to hnRNPs inhibits the RNA-binding ability of hnRNPs [16, 20, 22]. It was well documented that human hnRNPA1 strongly binds to a G-rich RNA element [23]. Similarly, it was found that Hrp38 could bind to a G-rich motif in the 5'UTR of DE-cadherin mRNA [20]. Incubation of human hnRNPA1 or Hrp38 with pADPr greatly reduced the amount of hnRNPA1 bound to its target RNA element [16, 20]. Collectively, these data demonstrate that PARylation of hnRNPs inhibits their RNA-binding properties, similar to the effect of PARylation on other RNA-binding proteins, such as NONO [24], Ago2 [25] and Poly(A) polymerase (PAP) [26].

1.3. Splicing Regulation by PARylation of hnRNPs

Experimental evidence has shown that PARylation can regulate hnRNP-dependent alternative splicing because hnRNP PARylation inhibits the RNA-binding ability of hnRNPs [16] (Figure 1). It is generally agreed that hnRNPs act as splicing repressors by binding to exonic/intronic splicing silencers (ESSs and ISSs) [27]. The inhibitory effect of hnRNPs on splicing is mainly attributable to the competition with S/R proteins for binding the regulatory elements. In some cases, however, hnRNPs were also shown to promote splicing by binding to exonic and intronic splicing enhancers (ESEs and ISEs) [28-30]. Since Hrp38 and Hrp40 knockout significantly increased the ratio of the spliced isoform to the skipped isoform of the *Ddc* (dopa decarboxylase) gene in *Drosophila*, Hrp38 and Hrp40 appear to function as splicing repressors for splicing this gene [16]. Similarly, PARylation of these two proteins by either *Parg* knockout or PARP1 activation promoted splicing of *Ddc* pre-mRNA by inhibiting hnRNP association with the splicing silencers of this pre-mRNA [16]. Hrp38s were also shown to function as splicing activators by promoting pre-*hsr ω* mRNA splicing [16]. However, Hrp38 PARylation by *Parg* knockout caused Hrp38 dissociation from the *hsr ω* pre-mRNA, thus inhibiting splicing [16]. Therefore, hnRNP PARylation can either promote or inhibit alternative

splicing during differently regulated splicing events, depending on whether hnRNPs function as splicing repressors or activators.

1.4. Splicing Regulation by PARylation of S/R Proteins

PARP1 can also modify SR (serine-arginine-rich) proteins in a noncovalent manner, including ASF/SF2 [15], SF3B1 [31], SF3A1, and SF3B2 [32]. It is generally agreed that S/R proteins function as splicing activators by binding to exonic splicing enhancers to antagonize the inhibitory effects of hnRNPs on splicing [33]. The SR domain of an S/R protein is often phosphorylated by SR kinases to regulate splicing. DNA Topoisomerase I (Topo I) was identified as one of SR kinases that phosphorylates the serine residues of ASF/SF2 and thus promotes alternative splicing [34]. It has been shown that pADPr can inhibit the kinase activity of Topo I, thereby decreasing phosphorylation of ASF/SF2 [15]. Mechanistically, pADPr polymers bind to ASF/SF2 either via RRM1 or the RS domain of ASF/SF2 to compete with Topo I for substrate binding [15]. Consequently, PARylation of SR proteins likely regulates alternative splicing by inhibiting phosphorylation of SR protein.

Figure 1. The model for the modulation of splicing by hnRNP poly(ADP-ribosyl)ation. Splicing enhancement by poly(ADP-ribosyl)ation of hnRNPs. In hypoderm tissues, the binding of Hrp38 and Hrp40 to the G triplets or quartets as intronic splicing silencers (ISSs) in introns 1 and 2 of the Ddc pre-mRNA inhibits splicing and results in exon skipping. The dissociation of hnRNPs from the transcript, such as the Ddc pre-mRNA, by poly(ADP-ribosyl)ation of hnRNPs induced by heat shock or elevated PARP1 activity in CNS enhances intron splicing.

2. REGULATION OF SPLICING BY PARP1 DURING THE TRANSCRIPTION PROCESS

2.1. Coupling Transcription with Splicing by Epigenetic Mechanisms

Genome-wide studies on splicing in yeast [35], *Drosophila* [36], and mammalian cells [37] have revealed that most splicing events are coupled with transcription. Co-transcriptional splicing implies that introns are spliced and that exons are ligated during the transcription process when the pre-mRNAs are still tethered to the DNA templates in the chromatin [1]. Because it takes longer to assemble a spliceosome than it does to complete elongation *in vivo*, splicing rate is much slower than the transcription elongation rate [1]. The key question for understanding co-transcriptional splicing is how the transcriptional machinery coordinates intron removal with the spliceosome before the termination of transcription. In addition, it is not clear what mechanisms recruit splicing factors to the nascent transcripts in order to achieve alternative splicing. Recent studies suggest that specific chromatin modifications may facilitate the coupling of splicing with transcription [38]. Eukaryotic chromatin is composed of highly organized nucleosomes formed by the core histones (H2A, H2B, H3 and H4) wrapping around the 146-bp DNA template. The N-terminal tails of histones undergo extensive post-translational modifications, including acetylation, methylation, phosphorylation, and PARylation, which modulate chromatin structure [39]. Changing the chromatin landscape has a profound effect on the status of transcription. Certain modifications, such as histone acetylation, lead to chromatin loosening, thereby facilitating transcription. In contrast, the heterochromatin, where transcription is generally repressed, is often marked by histone methylation, such as the enrichment of H3K27me3 on inactive X-chromosomes in mammals [40]. Similar to labeling active/ inactive chromatin regions, histone modifications are also found to facilitate splicing site selections by marking introns and exons [41, 42]. Nucleosome density is higher in exons than in introns [42]. For instance, trimethylation of Lys36 in histone H3 (H3K36me3) is preferentially associated with exons, not introns, in *C. elegans* [41] and human [42]. However, when compared to constitutively spliced exons, it appears that the alternatively spliced exons are marked with H3K36me3 to a lesser degree [41]. It has been proposed that histone codes can be read by an adaptor system, which then transmits the splicing signals from the chromatin to the spliceosome [43-46]. For example, the chromatin-binding protein MRG15 recognizes H3K36me3 in the alternatively spliced exon IIIB in the human fibroblast growth factor receptor 2 (FGFR2) gene and proceeds to recruit the splicing repressor PTB to the regulatory elements of this exon, repressing splicing [43]. The chromatin-associated protein Psp1/Ledgf can bind to H3K36me3 and recruit splicing factors for splicing regulation [46]. Another chromatin protein, CHD1, reads H3K4me3 (trimethylation of Lys4 in histone H3) codes and brings U2 snRNP to the chromatin, thereby activating splicing [44]. Because it was established that HP1a can recognize H3K9me3 in the chromatin [47], the interaction between HP1a with hnRNP proteins, such as DDP1, HRB87F and PEP, may represent another mechanism that brings hnRNPs to chromatin. Alternatively, transmission of the splicing signal from chromatin histone codes can be achieved by direct interaction between chromatin proteins and nascent transcripts [45]. For instance, HP1 γ can recognize H3K9me3 in alternatively spliced exons, such as CD44, to slow down the elongation rate of RNA polymerase II, facilitating exon inclusion [45]. It appeared that HP1 γ could also bind to the regulated pre-mRNA to effectively couple

transcription with alternative splicing [45]. In addition, the RNA-binding protein Hu can directly inhibit the activity of histone deacetylase 2 (HDAC2), thereby inducing local histone hyperacetylation [48]. Elevated histone hyperacetylation around the alternatively spliced exons made chromatin more relaxed, increasing the local transcription elongation rate and decreasing exon inclusion [48]. The aforementioned examples illustrate the multiplicity of mechanisms allowing the coupling transcription with splicing.

2.2. Chromatin Remodeling by PARP1

PARP1 plays a pivotal role in regulating chromatin structure [49,50]. Enzymatically silent PARP1 binds to the core histone proteins, thereby contributing to chromatin compaction for transcription inhibition [50]. PARP1 preferentially binds to H3 and H4 in mononucleosomes with linker DNA *in vitro* [18, 51]. H4 can activate PARP1, which, in turn, activates PARylation [18]. Activated PARP1 can PARylate itself, histone proteins, and other chromatin-associated proteins, leading to chromatin loosening, which facilitates the passage of RNA Polymerase II through the DNA molecule [13]. Phosphorylation of Ser137 in *Drosophila* H2Av histone variant (homolog of mammalian histone H2Az/H2Ax) induces PARP1 activation for transcription of such target genes as the heat shock-induced *Hsp70* gene [52]. In turn, phosphorylation of H2Av-Ser137 may stimulate the activity of dTip60, a histone acetyltransferase, leading to acetylation of H2AvK5, which facilitates the exposure of H4 tail for PARP1 activation [53]. PARP1 can modify histones and a number of chromatin-associated proteins, thereby modulating chromatin structure during transcription [54]. LPS (lipopolysaccharide) treatment of macrophages can stimulate PARP1-dependent transcription of inflammatory genes, including IL-1 β gene [55]. PARP1 can PARylate the histone demethylase KDM5B, thereby inhibiting its activity to maintain H3K4me3 levels in the promoter regions of the positively regulated genes [56]. A recent study showed that PARP1 interacts with a histone methyltransferase (Suz12) to maintain and localize it on the chromatin [57]. Therefore, inhibition of PARP1 activity by PARP1 inhibitor PJ34 can decrease the level of H3K9 and H3K27 modifications in pronuclei of male mice [57]. In addition, poly(ADP-ribose) can bind to the nucleosome remodeling ATPases, including ALC1 [58] and dMi2 [59], recruiting them to the transcriptionally active regions for modeling chromatin structure. Together, these studies suggest that PARP1 is the key regulator, modulating chromatin status during transcription.

2.3. Linking Transcription with Splicing by PARP1

As discussed above, PARP1 activation is required for the expression of inducible genes by making chromatin more accessible to the transcription machinery. Several lines of evidence support the hypothesis that PARP1 couples transcription with splicing directly. PARP1 activation leads to chromatin loosening in the ecdysone-inducible E74 puff in *Drosophila*, where both pADPr and Hrp40 are accumulated [16, 19]. Indeed, the first indication that splicing occurs co-transcriptionally came from the observation that the 60 kb primary transcript of the E74 gene was spliced to form 6.0 kb mRNA before transcription termination [60]. Histone modifications, such as H3 phosphoacetylation and chromatin remodeling by the chromatin

remodeling factor NURF301, are also involved in changing chromatin structure during the expression of ecdysone-inducible genes [61, 62]. Consequently, it seems plausible that PARP1 could couple chromatin remodeling and splicing by recruiting splicing factors, such as hnRNP proteins, to the transcription site during the transcription process (Figure 2).

3. PERSPECTIVES

Based on the experimental evidence summarized above, Poly(ADP-ribosyl)ation can regulate both transcription and splicing processes. Poly(ADP-ribosyl)ation of histones and chromatin-associated proteins mediated by PARP1 dramatically changes chromatin structure, facilitating the transcription of inducible genes during development. Poly(ADP-ribosyl)ation also regulates the interaction between RNA-binding proteins and their RNA targets to modulating alternative splicing. Therefore, PARP1 might function as an adaptor protein, transmitting histone modification information contained in chromatin to determine the splicing pattern by interacting with splicing factors, such as hnRNP proteins. However, several questions need to be addressed to further substantiate this assumption. Specifically, it is important to determine whether PARP1 preferentially recognizes specific histone codes, such as H3K9me3 and/or H3K36me3, in relation to exonic definitions. We might also ask 1) what role histone poly(ADP-ribosyl)ation plays in determining the transcription rates for splicing regulation and 2) whether PARP1 recruits splicing factors to the transcription sites in a pADPr-dependent manner. A detailed investigation of these questions will help us understand how splicing is coupled with transcription.

Figure 2. PARP1 binding to specific epigenetic marks in chromatin facilitates loading alternative splicing factors to specific locations of a pre-mRNA. Nucleosomes with specific epigenetic markers (red flags) localized in constitutively spliced exons preferentially bind PARP1 (blue snowman), which proceeds to attract splicing factors (magenta) and position them in the marked areas to cause exon skipping.

Chapter 28

PATENT ROADMAP FOR THE BIOSENSOR SPACE

Mohamed C. Azeez^{*,†}, Unisha Patel[†] and Dennis Fernandez

Fernandez & Associates, LLP, Atherton, CA, US

ABSTRACT

Genetic and behavioral data mining will revolutionize health/lifestyle delivery and outcomes, in much the same way the Internet delivered meaningful social outcomes by providing the infrastructure for information to be collected and connections to be made in ways that had not been possible hitherto. Genetic databases and lifestyle correlations via the cutting edge field of bioinformatics, wearable technology and personalized medicine will be the next echelon of information to be reconnoitered and used through the Internet to enrich our lives. Thanks to smart phones and wearable technology, it will all commence from the palm of our hands. In this review, we will spotlight the emerging fields of bioinformatics, personalized medicine and biosensor technology: historical insights, current issues, and future trends. In particular, we will embark on an in-depth look into the sub-fields of personalized medicine and wearable systems for health and lifestyle management. The health-sector, being information intensive, will exploit IT-led platforms that capture personalized health data in real-time and have connectivity with a cloud backbone to intelligently process the information to deliver real-time analytics and actions. Various roadmaps are presented offering aggressive offensive and defensive IP strategies and solutions to companies in the bioinformatics and biosensor space. How does current patent law and policy in the wake of the AIA reforms and Supreme Court decisions in *Alice* and *Mayo* impact on this field and on the strategic guidepost? What's more, we will reopen the patent troll reform debate: will it create a sweeping sea change, or be just another talking point. How do the sweeping provisions of Obamacare touch upon the field of wearable health systems and bioinformatics? Moreover, how can we reconcile proprietary value with the growing trends of the open-source movement and the big health data initiatives that lie at the intersection of private and non-profit sectors? Finally, all of this big health data begs an inquiry into issues of privacy and a host of other ethical concerns. With the right strategies in their IP toolkit, bioinformatics and wearable startup companies will not only bolster their current patent position, but also be able to leverage it into a

* Corresponding Author's Emails: azeez.iploft@gmail.com; unisha.iploft@gmail.com.

† Associates have contributed equally.

significant competitive advantage. More importantly, the broader public will be able to avail themselves of the utility of these flash-bulb popping innovations that promise to capture personalized health data in real-time to deliver targeted and improved health outcomes.

INTRODUCTION

“Imagination is more important than knowledge” - Albert Einstein

Albert Einstein’s proclivity for imagination over knowledge is an initial point, because science, medicine and Intellectual Property (IP) are based on the power of imagination. Einstein understood that it is the ability to “stand on an existing foundation of accepted knowledge, and see beyond to the next frontier of discovery that is the source of personal, cultural and economic advancement. [1] The World Wide Web in the past two decades has opened our eyes to a plentitude of information and thus, molded the present. Likewise, in the next two decades the avant-garde fields of wearable technology, bioinformatics and personalized medicine will be the next stratum of information to be explored and used through the internet which will change our lives and help us make healthier and smarter lifestyle decisions.

Bioinformatics has been defined as “the application of computing power to biological data to reveal new patterns and information below the surface of that data.” [2] The patterns emerging from this treasure trove of data have enabled a vast array of genomic and proteomic tools, such as high-throughput RNAseq-expression profiling, next generation sequencing for personalized medicine and mass-spectrometry-facilitated protein profiling, to single out sequence variants across an entire genome and global expression. [3] With this tool in the biomedical investigation toolkit, researchers are able to pinpoint the molecular variants underlying disease states, and use these leads for developing novel targets in the cure and prevention of the disease. Some tools include enabling data mining, visualization, sequence alignment, pattern recognition, molecular modeling, and predictive tools. What happens when these bioinformatics tools leave the confines of a lab setting and become integrated into ubiquitous consumer devices? A powerful array of dynamic provisioning will now be at our disposal- literally from the palm of our hands.

In the new economy, a brand's competitive advantage will be determined by how effectively its team can build a strong Intellectual Property portfolio to protect a robust suite of products. The rise in proprietary value around bioinformatics and wearable device technology has led to unprecedented investments, underscoring the strategic value of Intellectual Property. A recent report from a New York based database research firm has reported an investment of \$1.4 billion in the wearable technology sector. [4] Moreover, venture firms have sunk more dollars into gene therapies and genomics-based molecular diagnostics since 2010, \$715.8 million, than they did all of last decade, \$653.6 million, according to venture source. [5] The US Dept. of Health and Human Services is predicting the market for personalized medicine will reach \$300B by 2020; it's no surprise that many of the same analysts feel the sector is now entering into the inflection phase of the Gartner Curve for what some are calling "the internet of healthcare." Exploiting IT platforms in order to mine and curate across a broad spectrum of health data will be pivotal.

However, as in any emerging technology, the concept-to-commercialization pipeline is fraught with peril: from Supreme Court decisions, sweeping legislative reforms, and the all-enveloping patent troll pandemic. Buried deep under hundreds of pages of amorphous codes and guidelines, lays a strategic guidepost. This review will elucidate a roadmap that offers a variety of offensive and defensive patent strategy for this emerging technology space. With these strategies in their IP toolkit, bioinformatics and wearable companies will be able to circumvent the legal pitfalls, and grab the high-hanging fruits of innovation that are sprouting in this sector.

PERSONALIZED MEDICINE

“It's far more important to know what person the disease has than what disease the person has” -Hippocrates

As individuals, we all have a stake in personalized medicine. Today, we are at a genesis of a new epoch of personalized medicine. The medical community has long recognized the inherent uniqueness of patients as evidenced by the prevalence of specific disease entities within families and ethnicities, variable responses to medications, and diverse manifestations of a single pathology. [6] Nonetheless, the scientific community and the advances in medical therapy until the turn of the 21st century have generally employed a broad treatment methodology to a heterogeneous population rather than a unique treatment approach to an individual patient. This practice is changing very rapidly because of the completion of the \$3.1 billion Human Genome project, which has heightened the scientific community's understanding of the individual, thus enabling the practitioners to treat individuals and patients based on their personal and unique characteristics- a practice known as Personalized Medicine (PM).

History of Personalized Medicine

The concept of personalized medicine dates back to the late 18th century when Mendel discovered the hereditary traits. But, it was not until the middle of the 19th century, when the developments in chemistry and microscopy allowed scientists to begin to understand the underlying causes of disease. [2] Since then, major developments in science and technology have allowed healthcare decisions to become increasingly granular over time. [7] With the growth of the pharmaceutical and medical device industries in the 20th century, came the rise of genetics, imaging, and data mining. Midway through the century, observations of individual differences in response to drugs gave rise to a body of research focused on identifying key enzymes that play a role in variation in drug metabolism and response and that served as the foundation for pharmacogenomics. [7] More recently, the sequencing of the human genome at the turn of the 21st century set in motion the transformation of personalized medicine from an idea to a practice. [7] The mapping of the human genome has shown that while mankind's genetic make-up is 99.1% identical; a small 0.9% inter-individual genetic variability creates and accounts for the vast variability that exists within the human species. [6] The rapidly

growing arena of personalized medicine will now enable the scientific community to focus on the 0.9% inter-individual genetic variability and create precise and specific therapies and drugs to individuals rather than a population. Our understanding of genetics and the genome has been greatly enhanced by the overwhelming revolution in sequencing technology in the recent years. [8] Next generation sequencing (NGS) has been widely implemented for whole-genome sequencing, whole-exome sequencing, transcriptome sequencing, targeted region sequencing, epigenetic sequencing, and other sequencing. [9] NGS has significant clinical potential in studying and identifying novel cancer mutations as well as understanding hereditary cancer. Additionally, another important and noteworthy implication of NGS is to advance personalized cancer treatment. For example, NGS has been used in the detection of epidermal growth factor receptor (EGFR) deletions in non-small cell lung cancer, which showed important pathogenetic and clinical implications for patients with non-small cell lung cancer. [10] In an inspiring study, genetics researchers at Washington University implemented a whole-genome and transcriptome sequencing for a researcher in their team, who had adult acute lymphoblastic leukemia. [11] The cancer relapsed twice in 10 years from the time of first diagnosis. It is at this point his colleagues found a significant clue about the disease through next generation RNA sequencing. Their results showed that a normal gene, *FLT3* was wildly active in the leukemia cells. Fortunately, the drug Sunitinib, which is approved to treat advanced stage renal cancer, acts as a *FLT3* blockade. With Sunitinib treatment, his blood counts appeared to be normal and the cancer was in remission. These developments in genomics, together with advances in a number of other areas, such as stem cell therapy, personalized medicine, bioinformatics, medical imaging, and more recently wearable technology, are creating the possibility for scientists to develop tools to truly personalize diagnosis and treatment.

Landscape of Personalized Medicine

“An Ounce of Prevention Is Worth a Pound of Cure” -Benjamin Franklin

National Institute of Science (NSA) describes ‘personalized medicine’ as, “the use of genomic, epigenomic, exposure and other data to define individual patterns of disease, potentially leading to better individual treatment.” [12] Personalized medicine can be defined broadly as a model of healthcare that is predictive, personalized, preventive and participatory. [13] Moreover, PM can also be referred to as the tailoring of medical treatment to the individual characteristics, needs and preferences of a patient during all stages of care, including prevention, diagnosis, treatment and follow-up. [7]

Personalized medicine generally involves the use of two medical products – typically, a diagnostic device and a therapeutic product – to improve patient outcomes. A diagnostic device is a type of medical device. Diagnostic devices include both *in vitro* tests such as assays used in measurement of genetic factors and *in vivo* tests, such as electroencephalography (EEG), electrocardiography (EKG), or diagnostic imaging equipment. [7] Many medical device therapies are now capable of being tailored to specific patient characteristics. These individual characteristics include patient anatomy (e.g., size), physiology (e.g., nervous and cardiovascular systems, metabolism, reproduction) and environment of use (e.g., intensive care unit, home use). [7] Additionally, physiological sensors can be used to predict treatment responses for individual patients. For example, 3D printing has been used to create personalized

medical devices based on imaging of a patient's anatomy. [7] In addition, the advent of mobile and wireless capability, better sensors, interoperable devices, and the Internet have led to technologies that allow for more effective patient monitoring and treatment outside the traditional medical care setting of hospitals, chronic care facilities and physician offices, instead, more people are treated at home and at work and are better able to maintain their lifestyle and quality of life. [7] As a result of these technological advances, medical diagnostics and therapeutics can be more finely tuned to better meet the needs of individual patients. [7]

In the long run, personalized medicine seeks to reduce the burden of disease by targeting prevention and treatment more effectively. [7] With the help of personalized medicine, the health care management paradigm will focus on prevention, moving from illness to wellness, and from treating disease to maintaining health. [7] By improving our ability to predict and account for individual differences in disease diagnosis, experience, and therapy response, personalized medicine offers hope for diminishing the duration and severity of illness, shortening product development timelines, and improving success rates. [7] At the same time, it may reduce healthcare costs by improving our ability to quickly and reliably select effective therapy for a given patient while minimizing costs associated with ineffective treatment and avoidable adverse events. [7]

The Exigent Need for Personalized Medicine

“Declare the Past, Diagnose the Present, Foretell the Future” -Hippocrates

Despite the major advances in the medical and scientific field, we still are a long way away from understanding of exactly how and why different individuals respond to the similar treatments in a different way. One of the major shortcomings is the ‘One size fits all’ mentality that we are currently converging on. ‘One size fits all’ and ‘Evidence-based medicine’ approach rarely works- be it in clothing, shoes or medicine. For example, a patient being treated for high blood pressure or diabetes might be placed on one of a number of blood pressure or diabetes medications available in the market. The patient's doctor makes a decision about what medication to prescribe based on only general-population- evidence-centric-based information about what might actually work for that particular patient. If the prescribed medication does not work after a few weeks, the patient might be switched to another medication. This somewhat “trial-and-error” approach can lead to patient dissatisfaction, adverse and antagonist drug responses and drug interactions and poor adherence to treatment regimens. [7] Figure 1, illustrates an alternative to the “one-size-fits-all” approach to treatment, whereby treatment is personalized and tailored to complement the genetic and metabolic profiles of a patient.

Evidence-based medicine may provide transitory savings in the short term, but the same patient who takes the cheapest available statin today may very well be the patient costing us—the taxpayer, the policymaker, the thought-leader, the sister, the spouse -- big bucks when that patient ends up in the hospital because of improperly treated cardiovascular disease. [14] The repercussions of choosing short-term thinking over long-term results and cost-based medicine over patient-based are pernicious to both the public purse and the public health. [14] Thus, quoting Mark McClellan, the chief architect of the American health care policy, “Looking at a gigantic uniform solution for everything is never going to work”, we must advance ahead to the 21st century of patient-centric and cost-efficient based medicine, where we can situate our

emphasis on treating patients via the 'Dose selection based on genotyping and phenotyping of an individual' approach. [14]

Figure 1. Illustrates the effects of genetic and metabolic profiles on pharmacodynamics and the value of developing a personalized and tailored approach to treatment. ("Personalized Medicine." Bayer HealthCare Pharmaceuticals RSS. Web. <<http://www.bayerpharma.com/en/research-and-development/research-focus/oncology/personalized-medicine/index.php>>).

Today, with the rapid advancements in the field of genomics and bioinformatics navigating into the age of personalized medicine, people can be screened with a variety of molecular diagnostics to reduce the side effects, increase compliance and improve outcomes. Increasingly in the near future, clinical outcomes will be monitored more accurately using computers that can control thousands of variables to help the scientific community, researchers and doctors to identify precise treatments that matter the most to improve individual-patient care. [14] It has increasingly become obvious that we, as future citizens of this country need to approach the newfangled and novel era of personalized medicine by developing the studies, tools and metrics that will provide policymakers, thought-leaders and Congress with the ability to evaluate, support and use new medicines and medical technologies to improve patient well-being in a patient-based, cost-efficient environment.

We must provide the 21st century health care evidence so crucial to the decision process of policy-makers and the policy debate of thought leaders -- and must do so in a coordinated, rigorous manner via evidence-based policy approaches that will (i) recognize the value of medical innovation, (ii) support the healthcare provider and patient as an empowered technology assessors and finally, (iii) reflect the emerging science of personalized medicine, bioinformatics and wearable technology to develop state of the art approaches in documenting and improving patient well-being in a cost-efficient way. [14] It is imperative to recognize the importance of partnership between the state and federal levels along with health systems, hospitals and academic research facilities whose end goal is to achieve a healthcare system where, the 'Equality of care' is matched to the 'Quality of care'.

BIOINFORMATICS

"Everything is going to be connected to cloud and data... All of this will be mediated by software"- Satya Nadella

Bioinformatics has been defined as "the application of computing power to biological data to reveal new patterns and information below the surface of that data." [15] The recent and rapid advances in the past decade in genomics and next generation sequencing (NGS) is beginning to reveal a large number of possible new and rapid, low-cost ways to sequence the genome, thus creating an mammoth amount of genetic data. The patterns emerging from this treasure trove of data have enabled a vast array of powerful and dynamic provisioning to be at our disposal on demand- literally from the palm of our hands. The key is to accurately and efficiently transform this 'big data' to benefit individuals in a clinical setting. Bioinformatics will provide the hub and tools for data analysis, interpretation, and ultimately the translation of relevant data in personalizing clinical medicine. [17]

While this has been the common application for bioinformatics for the past decade and a half, this field has recently branched into lifestyle and well-being applications. Bioinformatics is no longer a place where just lab-based science meets information science, but now has become a place where real-time, on-demand, physiological data seamlessly integrates with information science, thus, translating the data into a comprehensive lifestyle and wellness program. For instance, BodySync's core Gene/Lifestyle Integration technology integrates and interprets nutrition, fitness, and lifestyle data into actionable diet and exercise information. [18] Health and lifestyle choices could be informed on a personalized and analytical level, the likes of which we have never seen before. This brand of medicine and healthcare, coined as P4 medicine by Leroy Hood, the famed geneticist, for being personalized, preventive, predictive, and participatory, will finally usher in cost-containment, efficiencies, and outcomes to a healthcare model that has largely been reactive and plagued by administrative inefficiencies and poor health outcomes. [19] The health-sector, being information intensive, will exploit IT-led platforms that capture personalized health data in real-time and have connectivity with a cloud backbone to intelligently process the information to deliver real-time analytics and action.

WEARABLE TECHNOLOGY

“Doctors can be replaced by software – 80% of them can. I’d much rather have good machine learning system diagnose my disease than the median or average doctor”- Vinod Khosla

Are wearables headed for humankind’s sixth sense? During his keynote speech at the most recent Consumer Electronics Show in Las Vegas, Intel CEO, Brian Krzanich, unveiled his mobile or wearable computing technology devices as varied from baby sensors that transmit bio-data to ear-buds that would enable runners to get detailed health information in real-time. According to Mr. Krzanich, smart wearable technology represents the newest iteration of the mobile market. [17] This new slice of the mobile market hopes to make the human-computer synergy more seamless, intuitive, and immersive.

Figure 2. The number of sensor units to ship and market projections for the sensor market for wearables. (Clarke, Peter. "Sensors for Wearables Market to Double in 2015." EE Times (Europe), 23 Oct. 2014. Web. <http://www.analog-eetimes.com/en/sensors-for-wearables-market-to-double-in-2015.html?cmp_id=7&news_id=222906773>).

Wearable products span across five distinct applications, across approximately twenty-three product categories. Two categories are assessed for the purpose of this article and are defined as follows: (1) fitness/wellness wearables monitor and track activity and emotions; and (2) medical/healthcare wearables monitor vital signs and deliver therapeutics. [20] The wearable device market is expected to experience exponential growth over the next few years. Market analysis and forecast organization, HIS, thinks that the Apple Watch, will stimulate and set a standard for fitness and health monitoring features on wearable electronics devices. [21] HIS predicts a seven fold increase in the shipments of sensors used in wearable electronics. Additionally, HIS forecasts the market for wearable equipment will move from 50 million units in 2013 to 135 million units shipped in 2019. [22] Figure 2, represents the sensor market for wearables in particular- notice the doubling of units in 2015 from 2014, and then an upward trend into 2019. It is forecasted to grow to \$8.3 billion by 2018, with an 18% compound annual growth rate. Research analysts predict that total volume will increase from 35.7 to 134 million

units in the same time frame (30% CAGR). [23] Wearables are projected to have the same market trajectory as tablet devices: 21% of all U.S. adults use some form of wearable, which is exactly the same market penetration of tablets in 2012. Today, tablet penetration is 41%, leading many industry experts to surmise that wearable penetration may double in the next two years, as well. [24]

If venture capital interest is any indication of future growth, then we are all poised to see unprecedented growth in the near future. As of June of 2014, there has been an unprecedented \$2.3 billion worth of venture funding directed towards digital health start-ups, of which \$200 million went to health wearables. [25] Intel Capital, Intel's venture arm, has just pledged to invest \$355 million in 16 carefully selected tech-start-ups. [26]

Lifestyle Wearables

In the next decade, wearable technology is set to become the next big frontier in the personal electronics market. Leveraging integrated wearable devices for personalized health and fitness applications will rely on latent-free connectivity and processing as well as low-consumption and high-fidelity sensing. In the context of motion sensors, multi-axis accelerometers and gyroscopes are being integrated with wearables in order to deliver higher accuracy body movement detection versus traditional accelerometer-only wearable designs. [27] These 6 and 9-axis motion sensors are integrated with microcontroller subsystems with an extremely low memory and power footprint. Most of the more resource-taxing processes are shifted to the microprocessor unit (MPU), relieving the microcontrollers of this resource stress. This sensor system architecture allows for highly differentiated accuracy, while still having a small form factor and a small resource footprint. [28] This type of sensor deployment in health monitoring is fast becoming an emerging standard due to the advances in circuits, microcontrollers, front-end amplification, and wireless transmission. Due to the miniaturization, sensors are increasingly being integrated into garments, socks, wristbands, watches, stickers, glasses, etc. Batch fabrication techniques, wherein microprocessors and radio communication circuits are integrated into a single circuit, have brought about significant reductions in size and resources. Future developments in the field of flexible electronics, as well as material science, will be the touchstone of smaller, lighter wearable systems. [29] Figure 3, demonstrates the vast ubiquity in product design, form-factor, and provisioning, with respect to lifestyle and health wearables.

Wearable systems integrate a plurality of sensors into a sensor network by relying on the 802.15.4/ZigBee and Bluetooth. This standard, based on low-power and low-cost radio frequency technology, has an exceptionally high data rate. The most ubiquitous wearable sensor for health and wellness applications is the accelerometer. It can very discreetly track metabolic activity, gait parameters, and general activities of daily living. It measures the acceleration of objects in motion along three reference axes. It's a far more preferred method to measuring physical activity, compared to a pedometer, because the intensity of the movement is more precisely captured. There is also data suggesting that precision rates can be optimized for activity based on sensor positioning; suggesting just how precise the data gathering can be via the accelerometer sensor. [30] In addition to displacement and velocity, accelerometers can also sense for orientation, inclination, body posture, etc. Since the first batch fabricated MEMS accelerometer in 1979, many advances have occurred in MEMS technology, not the least of

Medical and Healthcare Wearables

Unsustainable trends including aging demographics, chronic disease, cost of care, and caregiver shortage are driving a global healthcare crisis and even threatening the global economy. [36] Biosensors representing the technological counterpart of living senses have found routine application like blood glucose measurement, drug development, and to some extent DNA chips for expression analysis and enzyme polymorphisms. [37] The use of wearable monitoring biosensors allows a constant monitoring of physiological signals which holds a prodigious promise in early detection, diagnosis and immediate treatment of various diseases. Wearable biosensors are an amalgamation of wearables and biosensors. Biosensors are analytical devices, which detect an analyte by combining a biological component with a physio-chemical detector. The biosensor consists of three major elements: (1) a bio-recognition component (e.g., microorganism, nucleic acids, enzymes, antibodies, cell organelles etc.), (2) a transducer/detector element which works in a physio-chemical way that transforms the signal resulting from the interaction of the analyte with the biological element into a signal which can be readily measured and quantified, and (3) an electronic system which includes a signal amplifier, processor and a display/reader device that displays the results in a comprehensible manner. [38] The graphics of figure 4, illustrates the workflow from sample to provisioning in a standard health wearable or embeddable, including the elements of a biosensor and transducer, converting the physiological sample into digital signals.

Figure 4. Elements of a biosensor in a standard health or medical-grade wearable or embeddable. ("Biosensor." *Wikipedia*. Wikimedia Foundation. Web. <<http://en.wikipedia.org/wiki/Biosensor>>.)

These wearable biosensors can be worn on the body in the form of smart shirts, watches, thin bandages or even tattoos. One such company based out of San Diego, Electrozyme, uses a disposable biosensor attached to a watch that measures an individuals' sweat and communicates with the wearer of the watch when to replenish lost electrolytes, rehydrate themselves or even take a break from their workout all in real-time where, the results are displayed on the individuals' smart phone. According, to its co-founder Jared Tangney, sweat has more than 800

biomarkers. Electrozyme combines the chemicals released in the sweat along with standard fitness wearables that analyzes just physical data to provide useful, actionable information to the individual in real-time. The biosensor strip which can be attached to the wearable watch is a low cost screen printed strip which can be produced for less than 10 cents a strip. Screen printing technology is a widely used technique for the fabrication of electrochemical sensors. [39] This methodology is likely to underpin the progressive drive towards miniaturized, sensitive and portable devices, and has already established its route from lab-to-market for a plethora of sensors. [39] The past decades have seen enormous progress in electro-analytical chemistry with the development of ultra-microelectrodes, tailored interfaces, molecular devices and smart sensors. These developments have resulted in substantial popularity of electro-analyses and to their expansion into new phases and environments. [40,41] As we enter the 21st century, we do not want to rely on cumbersome electrochemical cells and bulky electrodes, but rather would like to have fast, small, easy to use, portable, economical and disposable electrode systems. [39] The exploitation of new fabrication techniques allows the replacement of traditional beaker type electrochemical cells and bulky electrodes with easy to use sensors. [39] Fabrication of printed devices on bendable substrates has enabled the development of a wide range of new electrode systems. [39] Screen printing technology is a well-established technique for the fabrication of economical, portable and disposable electrode systems. [42,43] The whole electrode system, including reference, counter and working electrodes can be printed on the same substrate surface. [44] Figure 5, is a schematic of the configuration of a portable and disposable printable electrode system.

Figure 5. Electrode configuration using a printed screen fabrication on a bendable substrate. (Hayat, Akhtar, and Jean Louis Marty. "Disposable Screen Printed Electrochemical Sensors: Tools for Environmental Monitoring." *Sensors* 14.6 (2014): 10432-0453. Web.< <http://www.mdpi.com/1424-8220/14/6/10432/htm>>).

The adaptability of screen printed electrodes is of vital importance in the area of research. The ability to modify electrodes with ease through different inks commercially available for the reference, counter and working electrode, allows for highly specific and finally calibrated electrodes to be produced for specific target analytes. [44,45,46] Briefly, a screen printed electrode comprises a chemically inert substrate on which three electrodes, including working electrode, reference electrode and counter electrode, are printed through screen printing methodology. [39] The working electrode is the principal electrode on which electrochemical reactions are performed, while the reference electrode and counter electrode are used to

complete the electronic circuit. [39] The chemical or biological event on the screen printed electrode is converted into a detectable signal with the integration of a transducer element. [39] The fabrication of an electrochemical screen printed sensor usually involves three steps: fabrication of the screen printed electrode, surface design of the screen printed electrode and subsequently utilization for a sensing application. [39] The inks used in screen printed electrode fabrication consist of particles, polymeric binder and other additives for improved dispersion, printing and adhesion process. [39] The exact ink formulation and composition are patented by the respective companies, and are not disclosed to the users. [39]

The rate limiting force in achieving the small form factor of any commercially available wearable or embeddable is its power supply. Endless thought has gone to figuring out how to put low-bulk, low-latency batteries that are long lasting, energy renewing, into small form factor devices. Innovations in energy harnessing methods have enabled wearable technology to overcome this rate limitation. Novel power circuitry has done to wearables, what the smart phone did to the Internet of Things, or to the sharing economy. One such source, with low vitality, but good enough for wearable sensors, is the energy-harvesting method called Piezoelectric. Here, a small power supply converts ambient vibrations into electric current, which is then stored in a rechargeable battery. This is particularly fitting with fitness-tracking wearables that incorporate accelerometer sensors. [47] Thermoelectric is another novel approach, which exploits body heat by converting it into low-yield power source. Again, while suitable for wearables, it would not be ideal for ambient sensors. [48] However, the most promising technique appears to be Wi-Fi backscattering pioneered by researchers at the University of Washington. Researchers have figured out how to employ currently existing Wi-Fi infrastructure to not only provide internet connectivity- but just as importantly- to power devices battery-free. Ultra-low power tags communicate intelligently with Wi-Fi enabled devices leaving a very small power footprint. [49] The tags communicate by altering and reflecting ambient carrier waves that are freely bouncing around us. These reflected signals are subsequently encoded and then decoded by other devices in the network. [50] Presently, data rates and signal range is highly limited in the beta stage, but backscattering is positioned to one day potentially overcome the form-factor limitation previously described, and fill a long-awaited void. Thus, the combination and permutation of modern thermoelectric, electrochemical and biochemical systems along with screen-printing technology offers an introduction of powerful and potential unprecedented tools for an effective monitoring of various diseases and health in real-time.

Diagnostic Wearables: Real-time Medicine

As mobile technology penetrates into the daily facet of our lives, its extension into the new types of technologies and devices is inevitable. A patient self-diagnosing themselves is a very tangible reality thanks to the rapid advances in wearable technology, where the applications are infinite. These wearables encourage its wearers to be more affianced in their own fitness, help modify lifestyle habits by reminding them to exercise or take their medication, while providing a platform for patients and their doctors to share data in real-time and collaborate in making healthy strategic decisions.

Here, we present a few examples of how diagnostic wearables in the next decade will help instantaneously relay data and health information to our doctors, thus aiding them to diagnose better.

- **Smart Contacts:** Imagine managing glaucoma by simply wearing a contact lens. Sensimed, a Swiss company has developed a unique non-invasive soft contact lens-based solution, which revolutionizes glaucoma management by providing an automated recording of continuous ocular dimensional change over 24 hours. The data is received wirelessly by an antenna that is further, transmitted from the antenna to a portable recorder, which is connected to the practitioner's computer via a Bluetooth.
- **Personal Heart Rate Monitor:** The products available in the market today to measure heart rate are bulky, uncomfortable and largely inaccurate. Cardiio, is a simple application that converts the front camera of an iPhone/iPad to measure heart rate from a distance without even touching the camera. It measures the slight increase in blood volume that causes more light to be absorbed, and hence less light is reflected from your face. [51] Cardiio uses the camera to track these tiny changes in reflected light that are not visible to the human eye and calculate heartbeat. [51]
- **ECG-recording Device:** Atrial Fibrillation can occur without the patient having any symptoms. It could be frustrating for cardiologists to monitor patients once every few months during their routine checkups. AliveCor's heart rate monitor is an easy-to-use, FDA approved and accurate ECG-recording device that attaches to the back of a smartphone and wirelessly transmits data to the AliveECG app. The AliveECG app helps inform clinical decision-making through immediate detection of AF in ECGs and patient engagement by tracking medications, symptoms and lifestyle activities. [52]
- **Otoscope:** Ear infections are one of the leading reasons for a pediatric visit in the US. 90% of all children in any given country will develop an ear infection before the age of 7. Imagine if you could just page Dr. Mom, instead of a pediatrician in the middle of the night. Cellscope [53] developed an Oto, a smartphone-based otoscope which lets parents capture images of their child's inner ear and transmit them over a secure server to the doctor who, based on the images, can decide whether or not to call a patient in for treatment or prescribe over the phone.

Therapeutic Implantables/Embeddables: The Future of Personalized Medicine

Wearable products like the Fitbit, Pebble smartwatch and Samsung Galaxy Gear are already on the market, and Google's Android Wear promises to bring all the power of a smartphone to your wrist. [54] Even as wearable technology readies for its day in the sun, the next trend of implantables are already on the horizon. And it promises to move us closer to a sci-fi future than anything we've seen so far. [54] According to Transparency Market Research, the market for wearable medical devices is expected to reach \$5.8 billion globally growing at a CAGR of 16.4% from 2013 to 2019. [55] Implantable, also referred to as "embeddable", technology refers to a class of objects that can be inserted directly into the human body to modify, enhance or heal in ways that non-embedded devices cannot. [54]

Proteus Digital Health took wearables to unabridged next level. They have developed an ingestible biosensor in the form of a pill, which directly reads onto a smart phone. Each pill contains a one-square-millimetre sensor that is coated in two digestible metals: copper and magnesium. [56] These metals are not dangerous to consume because they currently exist in multi-vitamin supplements, as well as naturally in our diets. [56] Upon swallowing, the sensor is activated by electrolytes within the body. [56] The pill then transmits a signal to a small,

battery-powered patch worn on the user's torso and sends the data via Bluetooth to a caregiver's or family member's smartphone. [56]

Here, we present few illustrations of how mobile technology has penetrated into our lives to help us better understand our future by helping us make smarter choices through the use of implantables and embeddables.

- **Healing Chips:** Currently, patients are using cyber-implants directly connected to a smartphone application in order to monitor and treat diseases in real time. A new bionic pancreas being tested at Boston University, for instance, has a tiny sensor on an implantable needle that talks directly to a smartphone app to monitor blood-sugar levels for diabetics. [57]
- **Ingestible smart pills:** The most vital feature of implantables is that it not only communicates with the smart phone but, will also have a tête-à-tête with their doctors. The future of patient-doctor relationship is going to be in real-time. Proteus Digital's research team is developing a cyber-pill embedded with microprocessors and biosensors which is made entirely of ingredients found in food and is activated upon ingestion which can text doctors directly from inside of a body and relay information to your mobile device via a body-worn patch.
- **Implantable birth control pill:** The hunt for a perfect contraceptive has gone on for millennia. [58] MicroCHIPS and a laboratory at MIT collaborated, licensed and developed a device which can be implanted under the skin of a woman, where a hormone normally used in contraceptives is dispensed into the body which can be turned on and off via a remote control. It is designed to last for up to 16 years, which is nearly half of a woman's reproductive life and unlike many existing contraceptive implants; it can be deactivated without a trip to the clinic and an outpatient procedure.
- **Smart Dust:** Perhaps the most startling of current implantable innovations is Smart Dust. [57] Arrays of full computers with antennas, each much smaller than a grain of sand, that can organize themselves inside the body into as-needed networks to power a whole range of complex internal processes. [57] Imagine swarms of these nano-devices, called motes, attacking early cancer or bringing pain relief to a wound or even storing critical personal information in a manner that is deeply encrypted and hard to hack. [57] With smart dust, doctors will be able to act inside your body without opening you up, and information could be stored inside you, deeply encrypted, until you unlocked it from your very personal nano network. [57] Thus, the future of implantables/embeddables is the next big frontier.

The Cloud and Home Automation as the Next Frontier: Analytics and Provisioning

As the sensor readings become more multidimensional, dynamic, and non-linear, there becomes an even more practical need for an intelligent, proactive, and context-aware analytics and provisioning. All of the various devices currently on the market, such as Fitbit, Nike Fuelband etc., come equipped with companion apps that deliver targeted health and lifestyle data and recommendations. However, the real utility is in the deeper analytics that provide

personalized risk assessments for both acute and chronic conditions and actionable targets based on comparative population data sets. Even deeper value will come from integration of these data sets into health systems and processes; aggregated wearable data can be integrated with other pertinent health information across certain geography, demography, and diagnosis to render a health diagnosis with sharper resolution. [59] What's more, cross-device or device-agnostic analytical platforms will be strategic in integrating a whole host of different wearable apps with varying standards and actionable data. [60]
